Viscous magmas can extrude with little explosive activity, forming lava flows and domal mounds. A vesicular rind, or carapace, can develop on their rapidly cooled outer surfaces, often forming a surface of blocky pumice rubble (Figure 2) underlain by obsidian or by nonvesicular lava. Continued cooling and crystallization of the flow increase the volatile content of the remaining liquid, which can then cause more vesiculation within the flow, often interlayered with nonvesicular rock. Buoyant masses of this pumice can forcibly pierce the overlying flow to the surface as pumice diapirs. Increased volatile content and resultant increased internal gas pressures can also form explosive craters on the surface of the flow and generate pyroclastic flows long after eruption has ceased. Pumice flows and domes typically are only a few square kilometers in aerial extent. Rock Mesa, a pumice flow in the central Cascade Range of Oregon, is about 6.5 km² (Fink and Manley 1987); and Mono Craters, a multiple dome and flow complex in east-central California, covers about 30 km² (Chesterman 1956). Pumices associated with domes and lava flows often have larger vesicles than other pumice types and can form blocks up to about 1 m in dimension. The erratic nature of vesiculation can make exploration and development difficult.

Air-Fall Deposits

Explosive eruptions eject fragments of dense magma, vesiculated magma (pumice), and country rock in various proportions and with various velocities and degrees of fragmentation. These fragments, and in many cases the deposits formed by them, are broadly referred to as pyroclastic.

Figure 2. Undisturbed surface of a pumice flow with rubble blocks up to 1.2 m in size on Rock Mesa, in the Cascade Mountains of Oregon. The flow lies within a wilderness area and is unavailable for commercial development.

In a Plinian-type eruption (named after Pliny the Younger's description of the AD 79 eruption of Mount Vesuvius), pyroclastic material is explosively ejected upward from the volcanic vent. The pyroclasts are boosted into the atmosphere by the explosion and maintained in suspension by convection, giving the appearance of a vertical column that flattens and spreads out at its top. Pliny the Younger compared its shape to that of a pine tree with a tall trunk (Bullard 1976). Based on grain size and dispersal characteristics, Walker (1980) concluded that some Plinian columns, or eruptive columns, may exceed 50 km in height.

Dense or large fragments leave the vent ballistically and fall at distances dependent on their exit velocity. Smaller or less-dense particles such as pumice lapilli and ash may be removed from the Plinian column by winds and cooled and deposited over wide areas, depending on column height, wind velocity and direction, and the particle size and density.

Air-fall deposits typically decrease in thickness and particle size with increasing distance from the vent and commonly contain pumice particles up to several centimeters. Air-fall deposits can blanket the existing topography over very large areas. Thicknesses range from tens of meters (those near the vent) to only millimeters (those several hundred kilometers away from the vent). Most commercial pumice operations use air-fall deposits.

Pyroclastic Flows

Decreases in eruption activity or overloading by continued eruption can cause the eruptive column to collapse either continuously or sporadically. The hot pyroclastic material falls from the column and flows outward from the vent following topography, and may flow more than tens or hundreds of square kilometers. Such pyroclastic flows can retain enough heat to fuse or weld the particles together after movement stops. The names applied to these rocks historically have included tuffs, welded tuffs, ash flows, and ignimbrites. Pumice fragments may survive intact on upper and lower surfaces that cool before welding occurs, but pumice fragments in the flow interior soften and collapse. Pumice deposits associated with pyroclastic flows tend to be thinner than air-fall deposits, and because unwelded portions are either easily eroded flow tops or are overlain by welded portions, pyroclastic-flow pumices are less frequently exploited commercially than air-fall pumice deposits.

Table 1. Uses of pumice

Use	Product Form and Processing	Essential Properties
Lightweight aggregate		
Decorative and structural concrete blocks; cast concrete; lightweight structural members, wall panels, floor decking; stucco and plaster mixes; pozzolan in cement; civil engineering, lightweight fill	Granular: crushing, screening, blending	Low density; good crushing strength; thermal insulator; acoustical insulator; fire resistance; moisture resistance
Abrasives		
Grill cleaners; scouring sticks for porcelain, tile, swimming pools; buffing wheel cleaners; cosmetic skin removal	Blocks: sawing, irregular lumps as mined	Broken vesicle (bubble) walls form sharp-edged particles; wear continues to generate fresh cutting edges
Stonewashing: water, pumice, and garments tumbled together in laundry machine; pumice must float; abrades and softens textile fibers	Coarse granular, ± 1.9 cm: crushing, screening	Broken vesicle (bubble) walls form sharp-edged particles; wear continues to generate fresh cutting edges
Hand soaps; scouring compounds; rubber erasers; polishing compounds for glass, metal, plastics; dental cleaners; wood finishing; nonskid paints; cleaning printed circuit boards; tumble polishing; leather finishing; matches and striking surfaces	Granular: drying, milling, screening, air flotation, blending	Broken vesicle (bubble) walls form sharp-edged particles; wear continues to generate fresh cutting edges
Absorbents		
Potting soils; hydroponic media; pet litter; floor sweep; turf aeration	Granular: crushing, screening	High porosity; large surface area; low chemical reactivity
Acid washing: impregnated with bleaching agents, tumbled dry with garments; requires high absorption rate; gas "charcoal" grills, absorbs fat and grease drippings	Coarse granular, ± 1.9 cm: crushing, screening	
Catalyst carriers; carriers for pesticides, herbicides, fungicides; screening; blending	Granular: drying, crushing, milling	High porosity; large surface area; low chemical reactivity
Architectural		
Loose-fill insulation; roofing granules; textured coatings; ground-cover resistance	Granular: crushing, screening	Low density; thermal insulator; acoustical insulator; fire resistance; moisture
Landscaping; decorative interior and exterior veneer	Blocks: boulders as mined; sawn slabs	Low density; easily shaped; low maintenance
Fillers		
In rubber, paints, and plastics; mold-release compounds; hot asphalt mixes; brake linings; screening; blending	Granular: crushing, drying, milling	Particle shape; cost
Filter media		
Both expanded and unexpanded forms used to filter animal, vegetable, and mineral oils; screening; firing; air flotation	Granular: crushing, drying, milling	Particle shape; expandability
Other uses include diluents; engineered fill; geotechnical uses; pottery clays	Granular: crushing, drying, milling	Absorbency; particle shape; expandability; sealing qualities

Epiclastic Deposits

Epiclastic processes include erosion, transportation, and redeposition by such mechanisms as water, wind, and mass movement. From a commercial standpoint, these processes can either degrade or enhance a pumice deposit. All could reduce pumice particle size and possibly intermix with nonpumice material, but wind and water can also sort by size and density and benefit the deposit by separating pumice from crystals and rock fragments. Movable thicknesses of pumice were produced in the central United States when surface drainage washed thin blankets of airborne ash into lake basins.

Scoria and Cinder Deposits

Scoria and cinder may be associated with many eruptive styles, but deposits exploited commercially are nearly all cinder cones. Cinder cones are unconsolidated piles of scoria and cinder formed by subaerial eruptions. Fresh cinder cones are typically conical, steep-sided, and often have a central crater. They are rather small volcanic landforms with diameters ranging from 100 m to about 2.5 km and heights from 30 to 500 m with slopes to about 30° (Wood 1980a, 1980b; Osburn 1982). Heights and slope angles are degraded with age and erosion, and composite cones of cinder and lava flows may have lower angles than cones of only cinders.

Cinder cones formed from a single vent can be nearly circular, but elongate forms can develop under strong prevailing wind condi-

tions or from fissure eruptions or multiple vent eruptions. Variations in color from red to black are often concentric around the vent. Cinders are black initially, but those deposited near the vent are subject to heating after deposition, causing oxidation of iron to shades of brown and red.

USES AND TECHNOLOGY OF PUMICE AND CINDER

Pumice and cinder at first appear to be interchangeable in many applications. In fact, each has distinct qualities that preclude direct substitution without some change in performance. Both are used extensively as lightweight aggregates in concrete products, but pumice produces lighter weight and lighter color whereas cinder produces greater strength. Pumice is used in abrasives ranging from screened material for stone washing to highly processed abrasives for polishing optical glass. The abrasive action of cinder is much too harsh for such applications. Cinder is used for road and highway aggregate and surfacing, but pumice of ten lacks sufficient mechanical strength to be similarly useful. Both are used as landscaping material but with obvious differences in color, weight, and texture.

Pumice

Table 1 summarizes the uses, processing, and essential properties of pumice. The largest volume end use in the United States is by far lightweight aggregate in concrete, followed by abrasives and

stonewashing. Because of the method used to collect production data, the lesser volume uses cannot be accurately ranked.

Lightweight Aggregate

Pumice is used as a lightweight aggregate in both cast concrete and concrete block units. Lightweight concrete reduces the total weight of the structure and reduces bearing strength requirements of the supporting members while contributing thermal and acoustical insulating qualities. Similar advantages are realized in plaster and stucco applications.

Decorative and structural concrete block units with pumice aggregate are easily handled, reducing construction time and worker fatigue. A typical $0.2 \times 0.2 \times 0.4$ m structural block with sand and gravel aggregate weighs about 17 kg (Figure 3). Commonly, a mixture of the two aggregate types is used to produce a block that retains the advantages of lightweight aggregate with an increased strength while sacrificing some of the weight advantage. A block unit with a 50/50 mix of pumice aggregate and sand and gravel aggregate weighs about 13 kg.

The light color of pumice is also advantageous in producing decorative blocks using mineral pigments. Blocks produced with broken surfaces, or split faces, exhibit a color contrast between the pumice particles and the pigmented cement matrix (Figure 4).

Pumice for lightweight aggregate is typically sold in sizes of <8 mm. American Society for Testing and Materials (ASTM) Standard C331 gives grading requirements (particle-size distribution) for concrete masonry units, but these may be waived for special applications that require particular texture, strength, weight, acoustical, or thermal properties. Grading is critical to the shrinkage characteristics of masonry units and is controlled in processing by crushing and dry screening.

ASTM Standard C331 also specifies unit weights of oven-dry material from 880 kg/m^3 for fine aggregate to $1,120 \text{ kg/m}^3$ for coarse aggregate. Lithic fragments must be limited to control weight, but obsidian fragments are deleterious because they may hydrate to silica gel, which expands and weakens the concrete. Organic debris and particle coatings of clay, iron oxide, or fine ash are also detrimental.

Suitable crushing strength of pumice particles is often tested qualitatively by hand or under foot, whereas quantitative measurements are made on masonry units. Schmidt (1956) reports ranges of compressive strengths and various other properties of concrete with pumice aggregate.

Pumicite and finely ground pumice are also added to concrete mixtures as pozzolanic material, an application distinct from lightweight aggregate. Pozzolans form cementitious compounds by reacting with calcium hydroxide, which forms as Portland cement hardens. Without the addition of pozzolanic material, calcium hydroxide can be leached from the concrete, causing it to deteriorate.

Abrasives

Pumice abrasive products are sawn and shaped blocks, granules, and powders, and bonded and reconstituted forms. The glassy vesicle walls are brittle; exhibit conchoidal fracture forming thin, sharp cutting edges; and have a Mohs hardness of 5.0 to 5.5. Fresh cutting edges are continuously generated as the friable pumice particles wear down during use.

Sawn and shaped blocks and irregular lumps of pumice are used in applications requiring handheld abrasives for scouring various surfaces. The United States Pumice Co. produces sawn blocks from its block pumice deposits on Mono Craters near Lee Vining, California. Large lumps and blocks of uniformly vesicular pumice,

Figure 3. Structural concrete block unit, $0.2 \times 0.2 \times 0.4$ m

Figure 4. An installation of pumice aggregate concrete blocks used as both structural and decorative elements. The smaller blocks are 0.1×0.4 m and molded with smooth faces. The larger blocks are 0.2×0.4 m with split faces formed by breaking apart a double block unit before the concrete has completely cured.

free of lithic fragments, crystals, and obsidian stringers, are sawn into rectangular blocks of various sizes. The $7.6 \times 7.6 \times 15.2$ cm blocks are sold under the brand name of Grillmaster for cleaning restaurant grills (Figure 5). The pumice gently scours the grill while neither scratching the metal surface nor removing the thin, seasoned layer that prevents food from adhering. Smaller blocks are sold for home use to clean porcelain and tile surfaces and for cosmetic skin removal. Pumice blocks and lumps are still used to clean buffing wheels, but demand has dropped with the decreasing use of chrome plating by the automotive industry.

Stonewashing of fabric—once the most rapidly growing segment of the pumice industry—is declining in favor of chemical or enzyme systems. Stone washing involves two distinct processes: abrasion, in which coarse granular pumice abrades the garment surface, and absorption, in which pumice acts as a carrier for bleaching chemicals. The term *stonewashing* is applied both to laundry use in general and to the abrasive process specifically in which finished garments, water, and pumice are tumbled together in large washing machines. The term *acid washing* refers specifically to the treatment

Figure 5. Scouring block produced by United States Pumice Co. from its Mono Craters deposit near Lee Vining, California.

process using pumice as a chemical carrier. Both processes use pumice particles of 2 cm to more than 8 cm. Smaller particles produce a more uniformly worn effect whereas larger particles impart a more irregular effect (Hoffer 1991). Each process requires pumice of different characteristics; acid washing is discussed in the section on absorbents in this chapter.

The abrasive process of stonewashing uses pumice particles with a low enough density and a low enough permeability to float in the laundry machine. The pumice must be hard enough to survive at least one wash cycle, but not so hard that it unduly damages the cloth fibers. Clean, light-colored pumice with few lithic fragments is preferred. The industry has a few standardized specifications. Often a new source of pumice is tested simply by using it—a potentially wasteful approach. Hoffer (1991, 1994) developed testing procedures to evaluate pumice for laundry use that measure particle density, absorption, surface fines, impregnation rate, and abrasion loss. Particle density and abrasion loss are the most important properties for stonewashing pumice.

The popularity of stone washed garments led to the development of many new pumice deposits, particularly in Turkey, Indonesia, and several Latin American countries. Traditional producers of aggregate pumice supply some laundry pumice, but many were unable to expand quickly enough to meet demand, some do not have pumice with appropriate particle sizes or other characteristics, and some are reluctant to make extensive modifications to their current operation and product mix to serve what is an ephemeral market driven by clothing fashions.

Pumicite and ground pumice are used in many abrasive products as loose granules and compounded in such products as hand soaps, rubber erasers, and polishing compounds for metal, plastics, and glass. Particle sizes for fine polishing compounds range from a few millimeters for non skid coatings to <100 μm . Consumer perception determines the particle size in some applications. Pumice is used in bar soaps, soft soaps, and liquid soaps, but products marketed for heavy-duty hand cleaning are more acceptable if they contain coarser pumice, giving a rougher texture in use. There may be differences between producers and particle-size distributions of respective grades, but abrasive pumice is still described by the system reported by Hatmaker (1932). Letters F through FFFF describe progressively finer particles from about 150 μm downward, and whole and fractional numbers from 0 through 10 are used for progressively coarser particles up to about 5 mm.

Most granular abrasives require uniformly finely vesicular pumice. Typically, the vesicle diameters are several times smaller than the finished product particle size (Figure 1E). Crystal, obsidian, and lithic fragment content must be very low to produce an abrasive with uniform hardness and wear characteristics. For example, pumice is used as an intermediate abrasive in polishing television tubes, optical components, and certain types of flat glass. It is used following grinding by coarser abrasives and is followed by final polishing with metal oxides. In a recirculating slurry system, any harder or tougher particles will accumulate to intolerable levels and produce scratches. Less than 1.0% nonpumice particles is required and less than 0.5% is preferred. Beneficiation to remove crystals, obsidian, and lithics is difficult, especially in fine particles, and few deposits have the low nonpumice content required.

Processing pumice and pumicite for abrasives involves drying, crushing, milling, air flotation, screening, and blending. Sizing is often done with wire or cloth screens and equipment designed for flour mills. Screening can be a difficult and time-consuming operation because the density, shape, and surface texture of pumice particles often cause clogging, or blinding, of the screens. Blending further controls product particle-size distribution. Abrasive pumice prices of up to 100 times aggregate pumice prices reflect the rarity of suitable deposits, the higher capital and operating costs of processing plants, and the higher product tolerances required for pumice abrasives.

Absorbents

The high porosity, large surface area, and low chemical reactivity of pumice make it suitable for many absorbent applications ranging from floor-sweep products to catalyst carriers. Processing ranges from simple screening to the same sophisticated techniques used to produce fine pumice abrasives.

Coarse granular pumice, +1.9 cm in size, is used to acid-wash garments. The pumice is impregnated with bleaching chemicals by various immersion and vacuum techniques and then tumbled dry with finished garments. The chemicals are released as the pumice touches the fabric. Unlike pumice for abrasive stonewashing, acid-washing pumice does not have to float and it must have sufficient porosity and permeability to absorb and release the chemicals. Surface coatings of fine ash or clays reduce the absorption rate, and the clays release the chemicals at a more rapid rate than pumice, causing uneven bleaching. Surface fines should be less than 5% by weight (Hoffer 1991). Iron oxides are also detrimental because they can be deposited on the fabric, producing a yellow or brown stain.

Lumps of pumice about 5 cm in diameter are used in gas grills to absorb grease drippings and reduce flaming. The pumice is marketed both as the manufacturer's original equipment in the grill and as a replacement product through retail outlets. These markets are shared with scoria, but both have declined in favor of steel plates.

Finer granular pumice is used in potting soils and as a hydroponic growth medium. Both the absorption and abrasive nonskid characteristics of pumice are valuable in its use as a floor-sweep material on machine shop or meat-packing plant floors. Finely ground pumice is also used as a catalyst support and carrier, and it is compounded with pesticides, herbicides, and fungicides to permit uniform application of small amounts of chemicals.

Architectural Applications

Pumice has architectural applications in addition to its use as lightweight concrete aggregate. Its low density, fire and moisture resistance, and thermal and acoustical insulating qualities make it useful in textured plasters and coatings, as loose-fill insulation, and as roofing granules. The high reflectivity of white pumice is also

advantageous in roofing applications. Coarse granules and pebbles as groundcover reduce the water otherwise required to maintain plant groundcovers, and pumice is distinctively colored and easily handled.

Large blocks and boulders of pumice are used in decorative landscaping. They are easily handled and can be readily fitted together or sculpted to specific shapes such as planters and lanterns. Pumice can be bored and hollowed for electrical and plumbing systems for fountains and waterfalls (Figure 6).

Pumice blocks are sawn on one surface and used as decorative veneer (cantera stone) on both interior and exterior walls, producing a highly textured, fire-resistant surface. The slabs can be shaped easily with hand tools for rapid and precise installation (Figure 7).

Density, pattern, and color are important for both landscaping and veneer products, but the most specific requirement is large block size. Few pumice deposits, primarily flows and domes, contain blocks of 1 m or more, and only one is currently in production in North America, by United States Pumice Co., a subsidiary of Featherrock, at Lee Vining, California.

Fillers

Mineral fillers are rock and mineral materials added to formulations to give products specific characteristics such as tensile strength in plastics, gloss (or lack of gloss) in paints, or weight and surface finish in paper. Typically, fillers are added as very fine powders, and many factors affect the choice of materials used.

The important attributes of pumice and pumicite as fillers are low cost, hardness, particle shape, particle size, absorbency, vesicularity, density, and low chemical reactivity. Permeable vesicular pumice particles are absorbent and can be used to vary viscosity, impermeable vesicular pumice can be used to decrease the density of the product, and platy vesicle wall fragments can increase tensile strength. The hardness of pumice can increase the abrasion resistance of the finished product, but it also increases wear on processing equipment. Very finely vesicular pumicite from Kern County, California, has been tested successfully as an opacifying agent to partially replace titanium dioxide in paints. Grading, or particle-size distribution, is critical to the performance of asphalt, and pumicite can be used to achieve the proper ratio of fines in asphalt mixes.

Filter Media

Liquids ranging from water, juices, and beverages to oils and fuels are clarified by filtration, which mechanically removes suspended particles. Filters can be beds of granular material (filter media) or granular material supported by porous membranes. Filter media can also be mixed into the liquid to remove more efficiently particles and to maintain porosity of the filter. Finer filter-media particles are required to remove finer particles from the liquid.

Pumice is useful as a filter aid because of its fine particle size, particle shape, low chemical reactivity, and, in some applications, expandability by pyroprocessing. Pumicite in Kansas and adjoining states is composed of broken vesicle walls, which are used to form a filter bed of overlapping plates to remove fine particulates (Figure 8A). Some of the pumicites can be fired and expanded into hollow spheres similar to those formed by expanding perlite (Figure 8B). The expanded pumicite is then milled to produce filter-media particles of specific sizes and flow characteristics.

Volcanic Cinder

The uses of volcanic cinder and pumice overlap in some applications, but cinder is not processed into as wide a variety of products as pumice. Volcanic cinder usually has thicker vesicle walls than pumice and produces a heavier but stronger lightweight concrete

Figure 6. Pumice landscaping boulders quarried from the Mono Craters deposit near Lee Vining, California, by United States Pumice Co., a wholly owned subsidiary of Featherrock, Inc.

Figure 7. Pumice veneer slabbed and palletized for delivery, Lee Vining, California

with insulating qualities less than those of pumice concrete of comparable strength and weight. Block units are gray or red depending on the cinder color.

Cinder and scoria are also used in the same construction applications as sand and gravel and crushed rock: base courses, road surfacing, asphalt aggregate, and railroad ballast. Cinder for these purposes must meet the same specifications as any other aggregate material, including abrasion resistance, immersion disintegration, and aggregate degradation. Cinders that qualify have a higher density than those used for lightweight concrete. The friable, fragmental nature of cinder deposits results in much lower production costs than from nonvesicular rock that must be crushed.

Cinders are also used to sand highways to improve traction on icy surfaces. Cinders are typically crushed and screened to sizes from about -16 to +4 mm. Coarser particles can damage vehicle windshields, and finer particles can retain moisture and freeze in stockpiles or during transit.

Cinders and scoria are used in landscaping as both placed boulders and coarse granular ground cover. Scoria blocks are also

used as building stones. Uniformity of color is of importance in landscaping and decorative uses. Scoria lapilli is used as an absorbent bed in gas cooking grills.

DISTRIBUTION OF DEPOSITS

The ephemeral nature of pumice and cinder deposits limits their occurrence to areas of geologically recent volcanism such as the Circum-Pacific belt, the Mediterranean region, and oceanic ridges. Table 2 lists sources of information on pumice and pumicite. Most of those tabulated have extensive lists of references to specific deposits and to more detailed descriptions.

Pumice lapilli deposits in the United States are largely confined to the area west of the Rocky Mountains, and airborne ash from this area has formed pumicite deposits throughout the Great Plains states. Pumice has been produced in the past for various pur-

poses from nearly every western state, including Hawaii, but currently mines in only six states are active. Table 3 lists pumice mines active in 2004 in the United States.

The principal pumice deposits are in north-central Arizona in the San Francisco volcanic field near Flagstaff in Coconino County. Several air-fall pumice lapilli and ash units occur in the area, and these have been mined for lightweight aggregate, horticultural, and laundry uses. In several other counties, epiclastic deposits of pumice and pumicite have been mined for lightweight aggregate and pozzolanic material (Hoffer 1991).

Chesterman (1956) listed and described more than 60 deposits of pumice and pumicite in California. All types of occurrences are represented, including flows, domes, air-fall, pyroclastic flow, and epiclastic lacustrine and fluvial deposits. Since the first recorded production in 1883, numerous companies have been

active throughout the state, producing pumice and pumicite for nearly every end use. Production from currently active areas illustrates this wide range of markets.

Pumice in the Glass Mountain Area of Siskiyou County in Northern California occurs as air-fall deposits and block pumice flows. Glass Mountain Pumice produces stonewashing pumice and lightweight aggregate from an air-fall deposit. Pumice for scouring blocks has been mined from Glass Mountain in the past, but the block pumice deposits are not being mined at present.

The Mono Craters deposit near Lee Vining in Mono County is a multiple dome and flow complex. The surface of the domes is a jumbled mass of pumice rubble at least 45 m thick through which spires and pinnacles of pumice protrude (Loney 1968). The flow surfaces are covered with loose angular blocks and exhibit complex movement patterns, and the flows terminate in steep talus slopes. Blocks of up to 2 m are mined by United States Pumice Co. for landscaping and decorative veneers. The company produces large blocks of coarsely vesicular pumice in a variety of colors and textures (Figure 1B; Figure 6). Smaller blocks are sawed into thin slabs for decorative veneer (Figure 7). United States Pumice Co. uses pumice of finer texture from the same deposit to produce abrasive blocks of several sizes for cleaning grills and ceramic surfaces and for cosmetic purposes. Small trimmings are sold for use in gas cooking grills, so there is very little waste in the processing operation.

California Lightweight Pumice Inc. mines water-laid pumicite in Madera County, in central California, and processes it for filler applications. Most of the pumicite particles in the deposit are <325 mesh (Chesterman 1956).

Pumice and cinder occurrences in Idaho are associated with volcanics of the Snake River region in the southern part of Idaho (Asher 1965). The active pumice mines are Producers Pumice near Idaho Falls and Hess Pumice Products north of Malad City in Oneida County, both of which supply graded material for lightweight aggregate. The Hess deposit is partially indurated, and the pumice is finely vesicular with a very low lithic and crystal content. From it, Hess produces high-quality abrasives for a wide range of markets, including glass polishing, metal finishing, soaps, and erasers.

Numerous beds of Pliocene and Pleistocene volcanic ash occur throughout the Great Plains states. The Valles Caldera, in the Jemez Mountains of northern New Mexico, has been identified as the source for much of the airborne material. The ash occurs as thin air-fall blankets and as reworked fluvial and lacustrine deposits with varying amounts of admixed detrital minerals. Some beds are altered to clays and others are composed of clean, unaltered glass fragments, nearly all of which are less than 100 μm .

Deposits in several states have been mined for abrasives, polishes, asphalt filler, absorbents, and ceramics. Some of the pumicites bloat into hollow spheres under proper heating conditions, and extensive testing has been done to produce filter aids and cellular glass blocks (Ham 1949; Bauleke 1962; Hardy et al. 1965). Currently, two companies are mining two different beds of expandable pumicite in north-central Kansas. Kansas Minerals, near Mankato, produces filter aids by drying, air classifying, and expanding the pumicite and milling the expanded fragments to the desired size ranges. Calvert Corporation, near the village of Calvert, sells a dried and screened product that its customers use in both expanded and unexpanded forms to filter vegetable oils.

Pumice occurs in several areas in New Mexico, but those deposits currently being mined are air-fall units associated with the Valles Caldera volcanics. Copar Pumice, C.R. Minerals, and others have produced lightweight aggregate, stone washing pumice, and material processed into granular abrasives. Several other areas of

the state produced pumice in the past, including East Grants Ridge near Grants in Cibola County.

Pumice production in Oregon is limited primarily to the Bend pumice, an air-fall lapilli unit around the city of Bend in Deschutes County. Cascade Pumice and Sierra Cascade produce lightweight aggregate, horticultural pumice, and landscaping material. Less than 5% of the fragments in the Bend pumice are greater than 2.5 cm in diameter, but Cascade Pumice screens this coarse fraction for stonewashing material.

A limited amount of pumice has also been produced from an extensive air-fall and pyroclastic flow unit formed when Mount Mazama collapsed, forming Crater Lake (Bacon 1983). The climactic air-fall lapilli unit now blankets an area of more than 5,200 km^2 with a thickness >1 m and an area of more than 900 km^2 at a thickness >3 m, with little or no overburden. To date, the Mazama pumice has not proven as satisfactory as the Bend pumice for lightweight aggregate, but some of it has been sold for stone washing material (Geitgey 1992).

Pumice deposits are distributed in other volcanic areas throughout the world. Historically, the relatively low value of lightweight aggregate has limited large-scale production to deposits such as those in Germany, Greece, and Italy that are near markets or near bulk transportation facilities. Increased industrialization has created greater markets for lightweight aggregates, and the higher value of stone washing pumice has led to the development of formerly uneconomic deposits. The following summary of international pumice occurrences is based on articles published in *Industrial Minerals* (Anon. 1977; Robbins 1984; McMichaels 1990), Harben and Bates (1984), various editions of the *USBM Minerals Yearbook*, and U.S. Geological Survey (USGS) Mineral Commodity data (Bolen 2004; Founie 2005).

The Italian peninsula is well endowed with volcanic rocks, but the country's most important commercial pumice deposit is on the island of Lipari, about 35 km off the northern coast of Sicily. An unconsolidated deposit of high-quality pumice has been the source of aggregate and industrial pumice for Europe and North America for many decades. Pumex SpA (Italy's largest producer) supplies lightweight aggregate, powders, and granular material for various industrial uses, and cosmetic stones. Italpomice SpA produces aggregate and stone washing pumice. Both companies can load directly from their operations onto ocean-going vessels.

Many of the islands of Greece, particularly the Cyclades and Dodecanese groups in the southern Aegean Sea, have pumice deposits. Several have been mined in the past, including Thera (Santorini), but production is now only on the island of Yali, where Lava Mining and Quarrying mines aggregate grade pumice for markets throughout Europe, North America, North Africa, and the Middle East. Yali is the principal source for lightweight aggregate pumice for markets on the U.S. East Coast.

Pumice exports from Turkey have increased over the last 10 to 20 years from almost none to an average of 832,000 tpy for the period from 2001 to 2004. Nearly all the production is stonewashing pumice, primarily for European markets. The deposits are located in relatively remote areas of central and eastern Turkey, and the pumice must be transported long distances by truck to ports on the Mediterranean Sea. Small amounts are used domestically for construction, and some companies are now producing granular and powdered material. Pumice mines are operated by about a dozen companies.

Many other countries produce pumice for both export and domestic use. Spain has active mines in the province of Ciudad Real and on Tenerife in the Canary Islands. Both Iceland and New Zealand are mining beyond local needs and are now supplying

various export markets. Several countries, including Ecuador, Guatemala, and Indonesia, are shipping stonewashing pumice.

Statistics

The United States had 16 domestic producers with 17 active operations in 2004, up 1 from 2003 (Bolen 2004; Founie 2005). The 16 producers operated in six states. There were 21 producers in 1985, 19 in 1986 and 1987, 20 in 1988, 11 in 1990, 14 in 1991, and 12 in 1992. Just more than 76% of production came from Arizona, New Mexico, and Oregon. The remaining production came from California, Idaho, Kansas, and Nevada.

During the period from 2000 to 2003, imports were mainly to markets on the East Coast and the Gulf Coast. Imports came from Greece, 80%; Italy, 14%; Turkey, 5%; and other sources, 1%.

According to the USGS, in 2003 world production was, by country: Algeria (500,000 t); Chile (850,000 t); Ecuador (90,000 t); France (450,000 t); Germany (500,000 t); Greece (1,700,000 t); Guadeloupe (210,000 t); Guatemala (260,000 t); Italy (4,500,000 t); Iran (1,100,000 t); Spain (600,000 t); Turkey (800,000 t); and 1,800,000 t were in other market economy countries. This is a total estimated world production of 14,400,000 t in 2003.

Both domestic and import sales of pumice and pumicite were affected by the 1991–1992 recession. Demand for lightweight concrete products decreased because of the decline of construction activity. A rebound in construction activity in the period from 1993 to 2004 increased domestic production of pumice and pumicite.

The most important markets for pumice and pumicite are building blocks, horticulture and landscaping, stonewashing, laundries, abrasives, concrete aggregate, absorbents, diluents, filter aids, roofing granules, water treatment, pet litter, engineered fill, geotechnical uses, pottery clays, and other unspecified uses (Table 1).

In 2004, about 76% of pumice was used by the building block industry. The remaining 24% was used in abrasives, millstones, abrasive wheels, laundries, aggregates, insulation, pesticide and herbicide carriers, roofing granules, and landscaping. Micronized pumice is used in toothpaste, polishes, soaps, and other applications where a high-gloss finish is required. Micronized pumice has individual particles with sharp cutting edges, even though the mineral itself is relatively soft.

The USGS estimates that identified domestic reserves of pumice and pumicite in the western United States exceed 25 Mt. The estimated total pumice and pumicite resources, identified and undiscovered, in the western and Great Plains states are at least 250 Mt, and may total more than 1 billion t.

All domestic mining was by open-pit methods and generally occurred in remote areas where land-use conflicts were not severe or were nonexistent. Mining and milling of pumice and pumicite generates reject fines that must be disposed of, but the environmental impact is restricted to small, remote geographical areas.

ALTERNATIVE MATERIALS

Nearly every end use of pumice and cinder has natural or manufactured alternative materials that have similar performance characteristics. Lightweight concrete is produced with blast furnace slag, expanded perlite, expanded clays, and air-entraining agents. Numerous minerals are used as granular abrasives. Clays, diatomite, and zeolites function as various types of absorbents and carriers. Other rocks and various manufactured materials serve for landscaping and veneer uses. Hollow microspheres of glass and plastic are used as low-density fillers, and diatomite and expanded perlite are used extensively as filter media.

The choice of pumice and cinder is often a function of costs—both production costs and transportation costs. Pumice and cinder

deposits typically are not indurated and relatively inexpensive to mine. Unlike perlite, expandable clays, and diatomite, many pumice uses do not require expensive pyroprocessing.

Pumice of various unique characteristics in some applications such as lightweight landscaping boulders and stonewashing that are not precisely matched by either manufactured materials or other natural rocks. Similarly, block and granular pumice occupy unique niches in the abrasive field because of their texture and friability.

PROBLEMS AND FUTURE TRENDS

Caution should be exercised in interpreting pumice and cinder statistics. Clear distinctions are not always made among various volcanic materials or their end uses, either currently or historically. Some reports cite only volcanic materials without specifying pumice, pumicite, cinder or scoria, pozzolans, or other volcanic rocks. Volcanics produced for construction materials can include pumice or cinder for lightweight aggregate, pumice or pumicite ground for pozzolan, and pozzolanic materials other than pumice. Uniform methods of data collection are impossible, particularly when production is sporadic, mines are in remote areas, or production is only for local use.

In the United States, mineral production statistics are reported to the USGS only on a voluntary basis. Through 1980, the USBM reported combined statistics of pumice, pumicite, and volcanic cinder. Since 1981, volcanic cinder statistics have been reported instead with crushed stone, a more accurate reflection of the principal market of cinder. The apparent abrupt decrease in production and number of producers in volcanic materials reflects a change in reporting procedures rather than a decline of the industry. The USGS has modified its pumice questionnaire to obtain more detailed data on specific products and markets.

Problems have arisen in the United States concerning acquisition of mineral rights to pumice on federal land. Many pumice deposits occur on federal land administered by the U.S. Bureau of Land Management for the U.S. Forest Service. Access to minerals is obtained by leasing, by staking mining claims, or by purchase, depending on the mineral. Leases and mining claims grant exclusive development right whereas saleable commodities are available to any purchaser. Leases require royalty payments; mining claims do not. Federal law has been modified over the years to specify which minerals are acquired by which methods.

Before 1955, pumice on federal land could be acquired by mining claims; and if the staking claims have been maintained, they remain valid. The Surface Resources Act of 1955 (U.S. Code, Title 30, Section 611) names sand, stone, gravel, pumice, pumicite, and cinders as common variety materials. As such, they can only be purchased; they cannot be acquired by staking mining claims. But the act also expressly excludes block pumice from the list of common variety materials, defining block pumice as pumice “which occurs in nature in pieces having one dimension of two inches or more.” Also excluded are “deposits of such minerals which are valuable because the deposit has some property giving it distinct and special value.” Many pumice deposits have some particles larger than 5.1 cm, but that may not necessarily qualify the deposit as block pumice. Stone washing pumice has a much higher value than aggregate pumice, but particles as small as 2 cm may be suitable. The courts and boards of appeal have given various, and sometimes conflicting, interpretations, and it is still unclear under what conditions, if any, exclusive mineral rights can be obtained for pumice found on federal land. Continued litigation is probable.

Future trends in pumice production will depend principally on building construction and fashion. Aggregate pumice remains the largest volume market, and sales fluctuate with construction activity,

which in turn is a reflection of general economic conditions. The appearance and softness of stonewashed garments remain in high demand, and as yet no satisfactory alternative to pumice has been developed. The higher value of laundry pumice has led to the development of new sources throughout the world, which may in turn lead to a more diversified pumice industry in those areas.

Pyrophyllite

Tadataka Hida and Ryuji Kitagawa

OVERVIEW

Pyrophyllite is a hydrous aluminum silicate that is generally described by the molecular formula $\text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2 \cdot \text{H}_2\text{O}$. This alteration mineral is light green or white with a waxy texture. In nature, pyrophyllite rarely exists in its pure form and is normally associated with accessory minerals such as quartz, kaolin, diaspore, corundum, andalusite, boehmite, sericite, chlorite, and alunite. Pyrophyllite ores can also include iron-containing impurities such as pyrite, hematite, and limonite; therefore, different mineral samples that are classified as pyrophyllite can contain various combinations of accessory minerals and have different chemical compositions. It is important to understand the origins and distributions of pyrophyllite deposits in order to extend pyrophyllite applications. This chapter therefore describes basic methods for the mineral's identification and analysis.

In Japan, pyrophyllite mined in the Mitsuishi District of the Okayama Prefecture was used in engraving from around 1800 until the early 1900s. With the introduction of primary school education in 1886, pyrophyllite ores began to be processed and used for slate pencils. During the 20th century, the demand for pyrophyllite ores as raw materials for ceramics—particularly refractory materials—grew in response to the increasing needs of industry. Quality checks during mining and strict quality control during the crushing and grinding processes are essential because the major, accessory, and trace ingredients of the raw ores determine the properties of the products, including refractory characteristics, coefficients of thermal expansion and contraction, melting point, hardness, and color.

Pyrophyllite ores have been used for many years in a range of applications. The quality requirements, however, have recently become much stricter as a result of competition from several minerals with similar properties. Consumption is also decreasing for a number of reasons, including advances in paper-manufacturing techniques, in which pyrophyllite is used as a filler; decreases in the number of dustings with insecticides because of improvements in agrochemicals; and the trend toward the use of longer-lasting bricks in the refractory industry.

Research is needed to expand the potential applications and, therefore, the demand for pyrophyllite ores. Low-quality ores might be used after removing impurities and by developing energy-saving furnaces that can operate at lower temperatures. In addition, advances in powder technologies are likely to increase the uses of

pyrophyllite ores in fine ceramics. Efficient usage remains important, however, because these ores have limited distributions and worldwide reserves.

CLASSIFICATION OF PYROPHYLLITE ORES

The name *pyrophyllite* derives from the Greek words *pyro* meaning *fire*, *phyllon* meaning *leaf*, and *lithos* meaning *stone*; it refers to the flaking or exfoliation that occurs on the surface of the mineral when it is fired. It is known as *roseki* in Japan, *nab-suk* in South Korea, *yelashi* in China, *agalmatolite* in North and South America, and *wonderstone* in special grades in South Africa. In Japan, pyrophyllite ores are divided into three main types on the basis of their mineral constituents: pyrophyllite, kaolin, and sericite (Table 1). This division is also applied to the ores in other parts of Asia.

PRODUCTION, CONSUMPTION, AND TRADE

Pyrophyllite is similar to talc in appearance, properties, and applications, and is generally grouped with talc in published statistics. Figures for pyrophyllite production alone are therefore often unavailable. Because it does not have an independent product classification from the World Trade Organization, there are no independent international trade statistics for pyrophyllite. It has been necessary to rely on the efforts of individual researchers and on limited regional figures. Furthermore, the figures for ore reserves, production, and consumption in China have many gaps, and China is passed over by current research despite its large share of global production. This chapter provides previously unavailable information on East Asia and Russia and covers pyrophyllite as a separate mineral clearly distinguished from talc.

Statistics

Global production of pyrophyllite ores in 2002 was an estimated 3 Mt, assuming a 1-Mt output for China and the United States, with Japan, the Republic of Korea, and China accounting for more than 70% of the total (Table 2). Japanese production fell slightly in 2002, to an estimated 600,000 t. This production was for use in refractories, ceramics, tiles, agricultural chemicals, cement, and glass fiber. Korea produced approximately 890,000 t that year, destined for use in cement (56.3%), tiles (7%), refractories (4.4%), ceramics (0.5%), and other applications (glass fiber, resin, etc., 17.9%), and 13.9% was exported for similar purposes (MOCIE 2003). Korean pyrophyllite ore exports were in the form of crude

Table 1. Classification and use of pyrophyllite ores in Japan

Large Grouping	Classification		Mineral Composition*		Usage
	Main Division	Subdivision	Main Constituents	Minor Constituents	
Pyrophyllite ores	Siliceous pyrophyllite	Siliceous P ore	Q, P	K, D, S	R, T, Cl, G

ore, shipped to Japan, Taiwan, and other countries in Southeast Asia. For reference, Chinese production was reported to be 623,000 t in 1991, for application in building materials, refractories, ceramics, agricultural chemicals, glass fiber, cosmetics, and other products (Zhu 1995). Other major producers are Brazil, India, the United States, Pakistan, Thailand, South Africa, and Peru.

Production Sites

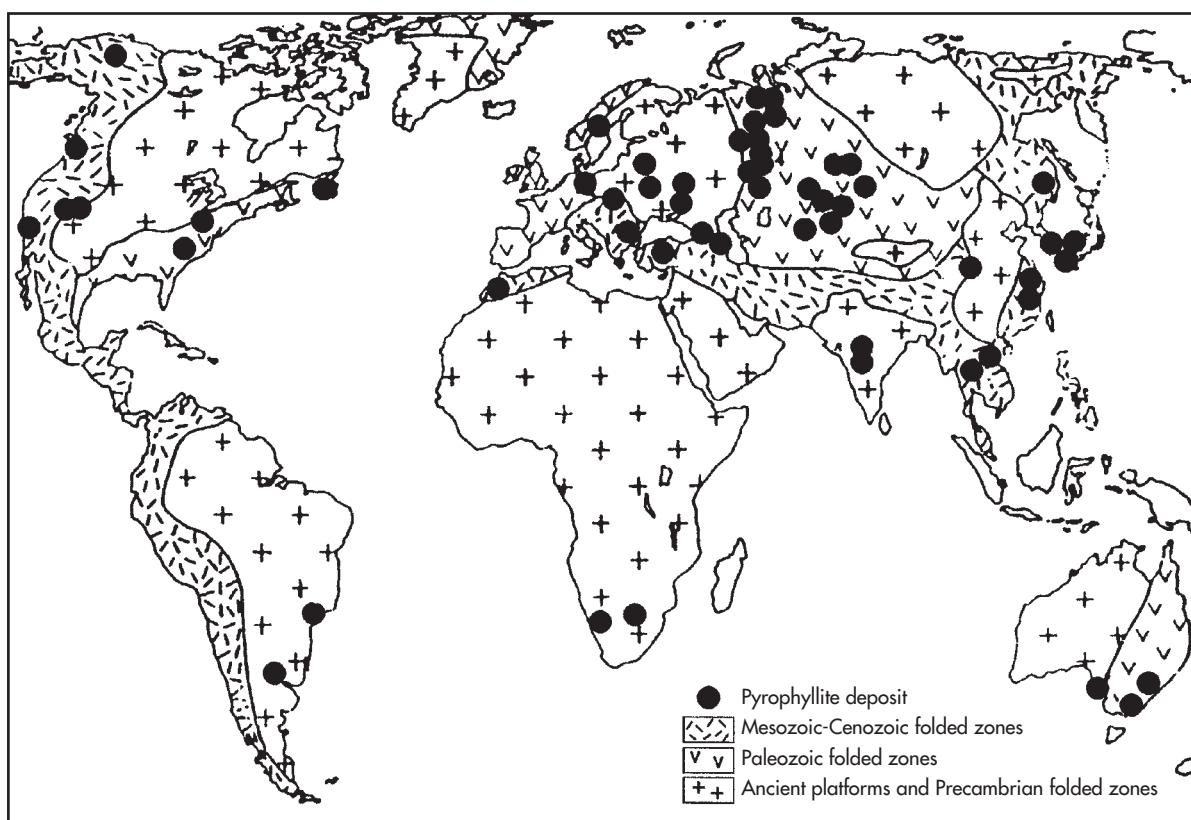

Most pyrophyllite deposits are found in subduction zones, related to plate movement, or in the region of old volcanoes formed at the site of collisions between tectonic plates. Global deposits are concentrated primarily in East Asia (Figure 1). These deposits originate from rhyolite and dacite formed in the Late Mesozoic and are relatively large and of high quality. Because of its natural properties, pyrophyllite ore is used principally in refractories. High-quality ore is used in making long glass fibers in East Asia; kaolin and silica sand are used for this purpose in the United States and Europe. Pyrophyllite ore is extracted mainly in low-cost open-pit mining, although some large-scale sites in both Japan and South Korea use trackless underground mining.

Japan

The main pyrophyllite mines in Japan are located in the prefectures of Okayama, Hiroshima, Nagasaki, and Hyogo. These deposits occur in rhyolite, dacite, and granite that is Cretaceous to Paleogene in age. In the Mitsuishi and Wake districts of the Okayama Prefecture, pyrophyllite ore is extracted by both open-pit and trackless underground operations. The ore is chiefly composed of pyrophyllite, quartz, sericite, and kaolinite. The Yano-Shokozan mine in Hiroshima Prefecture uses stepped-level open-pit extraction. The extracted ore consists of pyrophyllite, quartz, and kaolinite accompanied by diaspore, corundum, sericite, alunite, and other minor constituents (Matsumoto and Yano 1995; Hida et al. 1996). Reserves in this mine were approximately 18 Mt in 2004, with a production rate of 70,000 tpy for use in glass fibers, agricultural chemicals, cement, refractories, and pharmaceuticals.

South Korea

Hydrothermal alteration in the Late Cretaceous period formed the Korean pyrophyllite deposits, which are found in rhyolitic rocks. The main production sites are in the provinces of Chollanam-Do,

Figure 1. The distribution of main pyrophyllite deposits in the world

Chungchongbuk-Do, Gyeongsangnam-Do, and Gyeongsangbuk-Do. Proven reserves have been calculated to contain 1.96 Mt, and probable reserves contain 49.68 Mt, for a total of 51.64 Mt (Table 3). The main pyrophyllite mines in Chollanam-Do are in the districts of Nohwado (Wando mine) and Haenam (Bakam, Bugok). At the Wando mine, stepped-level open-pit mining and trackless underground excavation are used. The deposits generally contain pyrophyllite and quartz, accompanied by diaspore, corundum, kaolinite, and sericite (Naito et al. 1999). The Bakam and Bugok mines extract rock containing kaolinite, dickite, and quartz. Production showed a continuous upward trend until 2001 but has declined since 2002 (Table 2). Exports accounted for 13.9% of production in 2002; the principal destinations were Japan, Taiwan, Sri Lanka, Indonesia, and Malaysia for use in cement, glass fibers, refractories, and other applications (MOCIE 2003).

China

Acidic igneous rock of Mesozoic age is found throughout the coastal regions of China, where pyrophyllite deposits have formed in rhyolite and dacite. The main production sites are in the provinces of Zhejiang, Fujian, and Inner Mongolia. Chinese figures for 1985 show proven reserves of 16.09 Mt, probable reserves of 22.79 Mt, and possible reserves of 47.46 Mt, for a total of 86.35 Mt (Table 4). Fujian Province has open-pit mines at Emei, Shoushan, Luoyuan, Pingxi, and elsewhere. The Emei and Shoushan mines have seen the greatest development in recent years. In 1984, reserves in these districts were set at 4.81 Mt and 4.36 Mt, respectively. The extracted ore consists of

* na = not available.

pyrophyllite and quartz, together with diaspore and kaolinite. Principal uses are in glass fibers, refractories, and handicrafts. In Fujian Province, production figures for 2002 were reported to be 150,000 t; the majority of this was used for manufacturing glass fibers, both domestically and through exports to Japan and South Korea. Zhejiang Province has mining operations at Taishun, Qingtian, and Shangyu, among others. At the first two sites, corundum is mined along with pyrophyllite. Taishun is an open-pit mine, with reserves of some 50 Mt and an extraction rate of some 300,000 tpy, according to the author's survey in 2003, used principally in glass fiber production, refractories, and tiles. Known sites in Qingtian include Shankou, Lingtou, and Beishan, where underground mining is employed. At Shankou and Lingtou, the ore consists chiefly of pyrophyllite and quartz, whereas at Beishan, it also contains a relatively large amount of kaolinite. The production rate in the Qingtian District is approximately 120,000 tpy, and the main uses of this pyrophyllite are in glass fibers, ceramics, tiles, and crucibles. The data in this paragraph were obtained from a survey conducted by the authors in 2003.

Brazil

Known pyrophyllite mines in Brazil include those in the states of Minas Gerais, São Paulo, and Paraná. In Minas Gerais, deposits are scattered along a 64-km stretch and are in the form of lenses or podiform masses in sericite and sericite-chlorite schists. Demonstrated reserves of 5.7 Mt have been calculated (Ciullo and Thompson 1994). The agalmatolite contains pyrophyllite, sericite, diaspore, kyanite, and quartz; uses include refractories, ceramics, paints, and soaps.

India

Pyrophyllite mining is principally concentrated in the states of Madhya Pradesh, Uttar Pradesh, Rajasthan, Orissa, and Maharashtra. This pyrophyllite formed through hydrothermal alteration of Paleozoic clastic rock (Zaykov, Udachin, and Sinyakovskaya 1988). The main production sites are in Madhya Pradesh and Uttar Pradesh, with mineral reserves of 4.33 Mt and 3.05 Mt, respectively (Harpavat 1995).

Russia

Large deposits of pyrophyllite have been identified in the alteration zones adjacent to sulfide deposits in the Urals. Although these pyrophyllite deposits have not yet been developed, they have the potential for significant output. Recent testing and research to investigate how these deposits can be economically exploited indicate suitability for refractories and ceramics in particular.

Other Countries

Commercial pyrophyllite deposits in the United States are located in volcanic metasedimentary rocks of Precambrian age in the Piedmont plateau of North Carolina. The pyrophyllite is found with kaolinite, sericite, andalusite, topaz, and diaspore and with lesser minerals (Harben and Kuzvart 1997). The ore, which is extracted in open-pit mines, is used in the production of ceramics, refractories, pottery, and insulators.

South Africa has three reported pyrophyllite mines: the Witpoort and Wonderstone sites in Ottosdal, North West Province, and the G and W Base mine in Mpumalanga. The pyrophyllite ore is found in the form of lenses or strata contained in rhyolite. Wonderstone is black or gray and consists of pyrophyllite combined with kaolinite, diaspore, sericite, and rutile. The ores are used in the diamond industry and in ceramics and paper manufacturing (pitch control).

The only pyrophyllite mine in Vietnam is located in Tan Mai in Quang Ninh Province. Geological surveys from 1980 to 1985

Figure 2. Transmission electron micrograph of pyrophyllite crystals from Chistogor deposit in the Urals, Russia

estimated 28.81 Mt of proven reserves and 16.33 Mt of probable reserves, for a total of 45.14 Mt (Taran 1990). Production was 19,200 t in 1999. The ore contains pyrophyllite, kaolin, and quartz and small quantities of chlorite, alunite, and diaspore. Principal applications are for refractories and pottery, and some ore is exported to Japan for use in glass fiber and resin manufacture.

MINERALOGY AND CHEMICAL PROPERTIES

Mineralogy

Pyrophyllite is a soft mineral with a hardness of 1–2 on the Mohs scale, and its ores are easily processed into fine-grained powders. It is generally characterized as smooth and white, although it can range from white to yellowish, pale green, or light gray; this variation is thought to be due to differences in the trace elements present.

Pyrophyllite is a 2:1 phyllosilicate mineral that consists of an octahedral alumina sheet sandwiched between two silica tetrahedral sheets. The basal oxygen atoms are adjacent at the interlayer of the sheets, and the interlayer bonding forces are believed to be weak Van der Waals forces, although electrostatic attraction and hydrogen bonding are also indicated. The weak interlayer bonding forces account for the soft nature and smooth feel of pyrophyllite. Cleavage pieces bend easily and the material is only slightly elastic.

The ideal chemical formula of pyrophyllite is $\text{Al}_2\text{Si}_4\text{O}_{10}(\text{OH})_2$. Each layer is electrically neutral and interlayer cations are not generally present. In nature, the replacement of Si^{4+} in the tetrahedral sheet with Al^{3+} is common; in addition, the replacement of Al^{3+} in the octahedral sheet with magnesium (Mg), Fe^{2+} , ferric iron, and titanium (Ti) has sometimes been observed. The basal spacing of pyrophyllite is approximately 9.3 Å, and it has triclinic and monoclinic polytypes with interlayer spacing of 4.3 and 4.0 Å, respectively (Brindley and Wardle 1970). Hydrothermal synthesis revealed that the triclinic polytype forms at higher temperatures than the monoclinic polytype (Eberl 1979). The pure triclinic polytype is rare in nature, however, and the monoclinic polytype or complexes of the two are more frequently observed. Pyrophyllite also occurs in association with clay minerals such as kaolin, mica, and mixed layer minerals.

The three most common forms of pyrophyllite ore are massive aggregates with or without a transparency, schistose structures, and radial aggregates of needle-like crystals. Irregular platiform crystals are commonly observed under electron microscopy, whereas fixed platiform crystals are relatively rare (Figure 2). The gold (Au)

decoration method has revealed the growth pattern of the different pyrophyllite crystal structures through microtopography (Figure 3). In this growth pattern, massive aggregates and schistose structures are formed by an elliptic two-dimensional crystal nucleus growth mechanism; by contrast, radial aggregates are formed by a polygonal spiral growth mechanism. The exact form of pyrophyllite might depend on the environmental conditions present during growth.

Chemical Properties

Pyrophyllite consists of 66.60% SiO₂ (silicon dioxide), 28.30% Al₂O₃ (aluminum oxide), and 5.00% H₂O⁺. High-purity pyrophyllite, however, is rare both in natural and synthetic forms. Tables 5 and 6 show the results of chemical analyses of pyrophyllite from deposits in different countries. Slight differences in chemical composition are thought to influence the color of pyrophyllite ores; for example, the

Figure 4. Phase diagram for the system $\text{Al}_2\text{O}_3\text{-SiO}_2\text{-H}_2\text{O}$ at $P_{\text{H}_2\text{O}} = 1$ kbar

pale blue green coloration of the ore from the Russian Gay deposit indicates that chromium (Cr) might be a coloring factor (Table 5).

A number of researchers have investigated the $\text{Al}_2\text{O}_3\text{-SiO}_2\text{-H}_2\text{O}$ system. According to Hemley et al. (1980), the temperature of the equilibrium boundary between kaolinite and pyrophyllite at a pressure of 1 kbar varies as a function of the concentration of SiO_2 ; as the SiO_2 concentration increases, kaolinite becomes stable at higher temperatures (Figure 4).

Pyrophyllite is inert and electrically neutral and therefore highly resistant to most strong alkalis and acids. It can, however, be decomposed to gelatinous aluminosilica with sulfuric acid.

Physical Properties

Pyrophyllite shows high fire resistance, thermal resistance, and thermal conductivity. On heating, pyrophyllite dehydroxylates at 700°C and changes to a metastable phase. This dehydration is accomplished by the loss of an OH^- group between the octahedral and tetrahedral sheets. On further heating up to $1,200^\circ\text{C}$, pyrophyllite decomposes to cristobalite and mullite; the latter has a hardness of 7–8 on the Mohs scale. Thermal characteristics vary between pyrophyllite ores, however, because of differences in their mineralogy and chemical composition. This variation contributes to the wide range of applications of pyrophyllite ores.

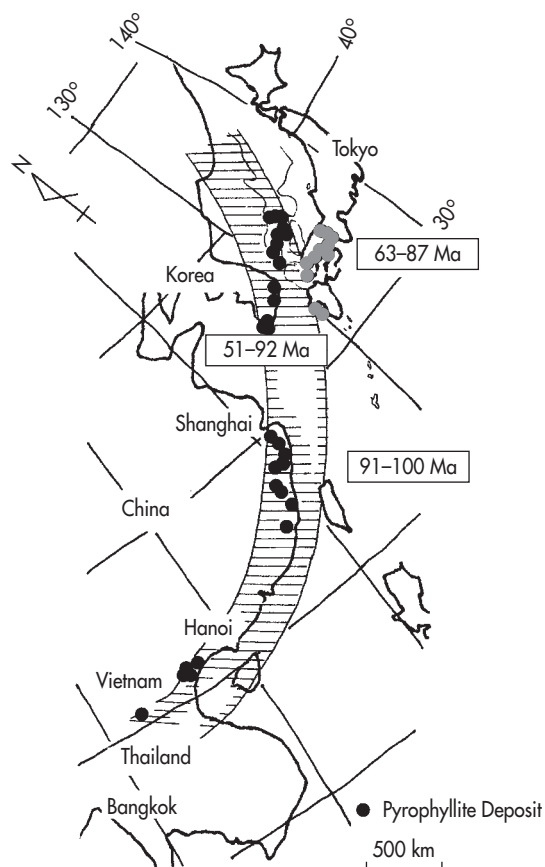

Because the water content of pyrophyllite is lower than that of other clay minerals such as kaolin, calcining is unnecessary. In addition, the coefficient of thermal expansion of fired pyrophyllite is lower than that of clay, resulting in more durable refractory products (Harben 2002).

GEOLOGY

Distribution and Formation Age of Pyrophyllite Deposits

Pyrophyllite deposits are mainly found in East Asia and the Ural District of Russia. Many of the East Asian deposits are distributed in the Japan–South Korea–China–Vietnam belt, which extends for more than 4,000 km; these deposits are largely concentrated in Japan, South Korea, and China (Figures 1 and 5).

No single report collates the dates of formation of pyrophyllite deposits worldwide. Several published studies describe the formation age of deposits in Japan on the basis of potassium–argon (K–Ar) radiometric dating of associated illite (Shibata and Fujii

Source: Kitagawa, Nishido, and Takeno 1988; Kitagawa et al. 1999.

Figure 7. Geological characteristics and occurrence of pyrophyllite deposits in East Asia

1971; Shibata and Kamitani 1974; Kitagawa et al. 1999); these range from 100 to 25 million years ago (Ma) (Cretaceous and Tertiary). Most of the pyrophyllite deposits in the Chugoku Province of southwest Japan range in age from 87 to 63 Ma (late Cretaceous and early Tertiary; Figure 5). In South Korea, pyrophyllite deposits are found in the southwest and southeast; the larger deposits are concentrated in the southwest, and their formation ages range from 92 to 51 Ma (Kitagawa, Nishido, and Takeno 1988). In China, the formation ages range from 100 to 91 Ma (Kitagawa et al. 1999). These data suggest that the formation ages decrease from China to South Korea to Japan.

In Russia, pyrophyllite is found in sulfide deposits scattered throughout a belt of approximately 2,000 km along the Ural Mountains (Figure 6). K-Ar radiometric dating of sericite in the deposits estimates the formation age at about 300 Ma near the end of the Carboniferous age (R. Kitagawa, personal communication).

Geologic Occurrence and Genesis

The shapes of pyrophyllite deposits can be roughly divided into massive, sheet, lenticular, and vein. The massive ore deposits tend to be the largest, as the name suggests, and also are the most common. Pyrophyllite is generally formed by hydrothermal alteration, and its primary origins are as follows: first, the hydrothermal alteration of volcanic rocks such as rhyolite, dacite, andesite, and tuffs, in which associated granites are assumed to be the heat source; second, the top or upper parts of an intrusive body, such as quartz por-

phyry, which acts as the heat source and is affected by hydrothermal alteration; and third, the alteration zone of metallic ore deposits.

In Japan, South Korea, and China, many deposits are distributed on the rim of circular structures with diameters of 10 to 35 km (Figure 7). These deposits are probably formed by hydrothermal activity at the marginal part of the caldera in a process closely related to caldron formation (Kim and Nagao 1992; Ishihara and Imaoka 1999).

Pyrophyllite from the alteration zone of metallic ore deposits, such as the Kuroko deposit in Japan, is not mined because of the small quantities present. By contrast, the body of pyrophyllite in the hydrothermal alteration zone of the Russian Ural sulfide deposits is large enough to be mined. Pyrophyllite has also been found in the quartz vein of a gold deposit in Russia, although too little is present for mining. In addition to the methods described above, pyrophyllite can be formed by alteration in a geothermal field; such deposits occur in Japan but are not mined (Kimbara 1991).

TECHNOLOGY

Exploration

Basic prospecting for pyrophyllite begins with selecting a suitable area for exploration using the available geological information. The geological features of the target area, such as lineaments, faults, and calderas, are then confirmed using satellite imagery and aerial photographs. The Advanced Spaceborne Thermal Emission and

Reflection Radiometer (ASTER) sensor onboard the Terra satellite measures light rays from visible to thermal infrared wavelengths, which allows the identification of rocks and minerals. This technique can be useful in exploration. In undeveloped areas, it is important to identify sites that might be dangerous or difficult to investigate. First, a broad geological survey is carried out in the target area with a topographic map, investigating the following parameters: the extent of the deposit and the host rock, the distribution of the surrounding rocks, and the geological structure of the area. Second, a more localized region is chosen for closer examination. A detailed geological survey, including drilling, is then used to determine the three-dimensional shape of the pyrophyllite deposit. Once drilling defines the deposit, underground development is performed. Third, a detailed map of the deposit is produced through analysis of the drill core and samples taken during the underground development. If the pyrophyllite deposit is near the surface, it is also useful to excavate trenches several meters wide. The most efficient methods for calculating the tonnage and grade are selected at this stage. The pyrophyllite deposits of East Asia are of relatively high quality and large scale and often show the characteristics listed below (Matsumoto and Yano 1995; Hida 2000):

- Found in rhyolitic or dacitic rock of Late Mesozoic age
- Marginal to, or overlapping part of, a volcanic basin or caldera
- Sited in the specific layer of overlaying shale or unaltered rhyolitic rocks
- Lenticular or stratified in structure concordant with the host rock
- Zonal distribution of the mineral assemblage
- Deposit controlled by faults and fissures

Evaluation

The results of the field survey, drilling, underground exploration, and trenching determine the geological structure, form, and zonal distribution of mineral assemblages. Mineral identification, chemical analysis, thermal analysis, and calcination testing then allow the grade distribution of the deposit to be determined in detail and the ore reserve to be calculated. The production grade can be predicted for the early, middle, and late stages of mining, and the mine plan can be made to fit user requirements for grade and quantity. It is important to evaluate the location of the mining area; in addition, the mine plan, investment requirements, and management strategy must all be accurately determined.

Mining

Pyrophyllite is mined using either open-pit or underground methods, both of which involve the use of large equipment. Bench-cut and inclined-slope techniques are used in open-pit mining. After blasting, the ore is classified on the basis of megascopic observations of the ore's size and quantities of alumina and iron present determined by chemical analysis. The blasted ore is loaded using hydraulic-power shovels, and dump trucks transport it to the processing plants. Some deposits must be mined using underground methods because of their shape and ore grade. The room-and-pillar method is generally used in relatively large mines. Underground mining is common in the Qingtian District of the Zhejiang Province of China and in part of the Nohwado island area of the Haenam District, Chollanam-Do Province, Republic of Korea. In East Asia, electric trolley trains, motorized bicycle-drawn carts, and dump trucks transport the extracted ore through transportation tunnels to processing plants outside the pits.

Ore Dressing and Processing

Both dry and wet processing methods are used in dressing pyrophyllite ores. The flow diagram in Figure 8 shows the dry and wet grinding processes used by the Shokozan Mining Co. Ltd., a major manufacturer of pyrophyllite powder products in Japan. This system is effective because the ores produced in the area are soft and contain relatively large amounts of clay-sized material. The ores are first crushed in a dry system to a particle size of less than 60 cm by a breaker at the working face or stockyard; they are then further reduced to 30 mm or less by a jaw-and-cone crusher. Particles of between 40 and 150 mm pass through the picking section, where corundum-bearing pyrophyllite and waste ore are sorted by hand; the former is valuable for use in specialized refractories and in some glass industries. Material less than 40 mm is screened to identify particles of the size required by manufacturers of tiles and refractories. Smaller clay particles (<1 mm) produced by drag classifiers and filter presses in the wet system are used in the manufacture of bricks, cement, and roof tiles. The water from the filter-press process is recycled to the screen process, and it is not discharged from the plant.

Pyrophyllite powder for use in agriculture and in the manufacture of glass fiber and plastics is produced by crushing ore to less than 30 mm and, for some customers, grinding it to -325 mesh in a roller mill. Accurate analysis of Al_2O_3 values and quality-control testing are essential when producing clay for glass-fiber applications; these processes account for a large proportion of the total cost of the products.

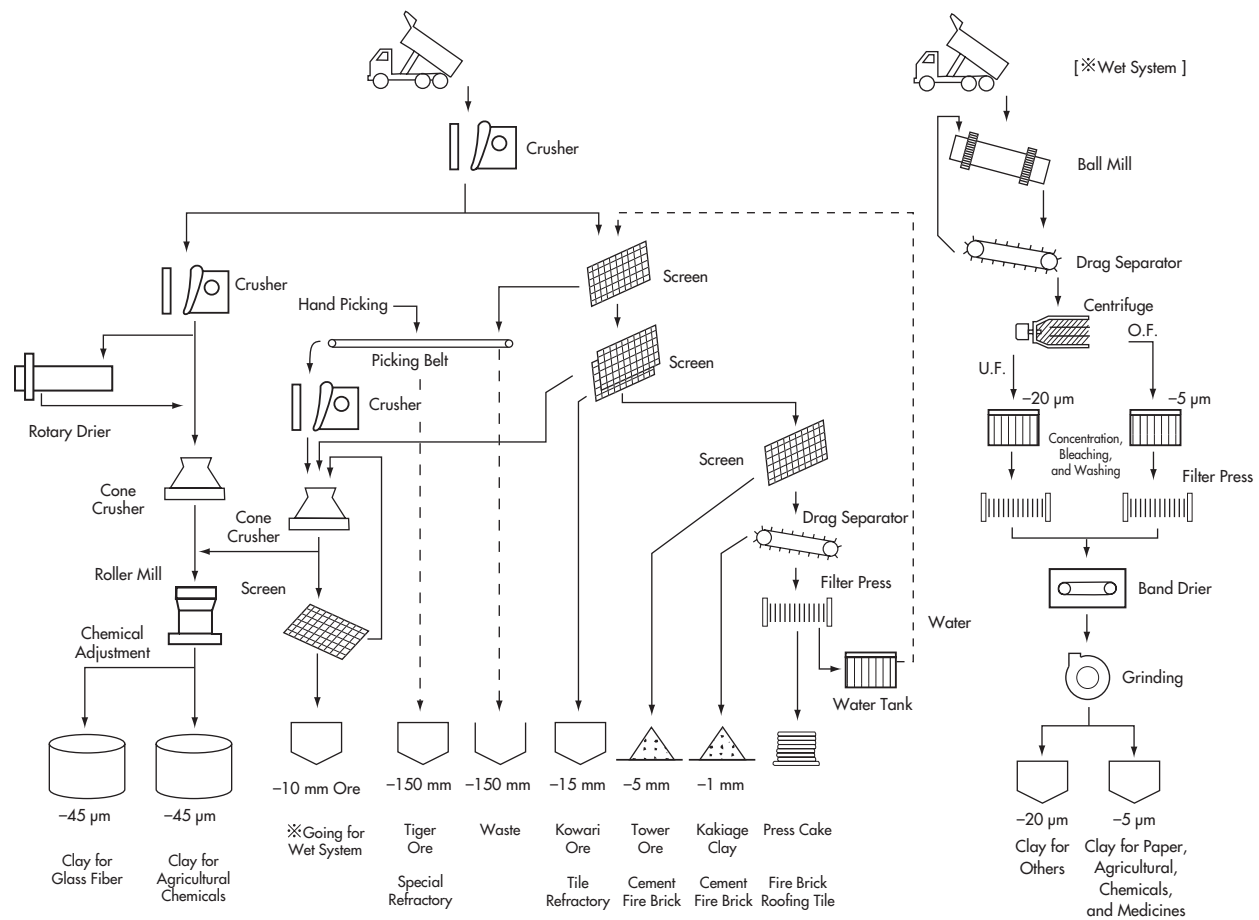

Pyrophyllite powder for use in medicines, paint, and construction materials is produced using wet processing. High-quality ore is crushed to a particle size of less than 10 mm and then ground in a tube mill. The fine pulverized powder, from which all quartz and heavy metals have been removed using a drag classifier, is then sent to a water tank, where aluminum sulfate is added to remove iron and bleach the powder. After being washed in clean water, passed through a filter press, dried to noodles, pulverized, and packed into bags, the powder is ready for shipment. The wet method is rarely used in East Asian countries, such as Japan, because of the costs of wastewater treatment; instead, dry grinding with a roller mill based on air elutriation is commonly used. By contrast, several of the beneficiation methods used to remove heavy metals and quartz in North Carolina (United States) and Newfoundland (Canada) are based on wet systems (Collings and Andrews 1990).

Packaging

Powder products are temporarily stored in product silos and packaged according to the exact specifications of the customer. Appropriate packaging materials for delivery to consumers include tank lorries, flexible container bags (500 to 1,000 kg), polypropylene (PP) bags (40 to 50 kg), and paper bags (20 to 25 kg). The automation of this process has improved rapidly in recent years with the development of automated equipment for both packing and loading. Automatic filling machines and flexible container bags have greatly reduced the labor and costs involved in the packaging process.

Transportation and Distribution

Using containers for the overseas transportation of pyrophyllite is beginning to expand. It is common to distribute material directly using tank trucks to larger customers in Japan; for smaller consumers, the networks of major trucking companies are often used, and some companies set up their own stock points in customer "hot spots" from which they distribute these products. Distribution costs are a significant issue for long-distance transportation, and one

Figure 8. Flowsheet for crushing, screening, and grinding of pyrophyllite ore

method of minimizing this expenditure is to take advantage of the backhaul to the area of the customers.

MARKETING

Uses

Pyrophyllite is used as a refractory raw material for various products, including pottery, porcelain, and tiles. It is also used as a clay material in cement, glass fiber, agricultural chemicals, building materials (mortar), paints, cleansers, rubber, medicinal clay (poultice), electrodes, resin fillers, and paper production as filler and coating. Strict quality control is necessary, both in the mine and during the crushing and grinding process, to ensure that the accessory mineral and trace element contents meet the specific requirements for different applications. Good care should also be taken to maintain product quality in transportation and other logistic operations. In the future, the range of uses of pyrophyllite is expected to expand with advances in the development of technologies in the chemical industry.

Specialized Uses

Pyrophyllite is occasionally associated with nacrite, barite, tourmaline, topaz, kyanite, zirconite, apatite, dumortierite, cookeite, vanbergite, or gold (Cornish 1983). Corundum-bearing pyrophyllite from the Shokozan Area of Japan is used for specialized refracto-

ries and in the glass industry. Diaspore-bearing pyrophyllite from the Mitsubishi Area of Japan, which is spherical or massive in shape, has applications in crucibles and specialized refractories. Dumortierite-bearing pyrophyllite from the Milyang deposit of South Korea is hand sorted for use in refractories. Kyanite-bearing pyrophyllite, which is chiefly mined in Brazil, is used in fillers and ceramics. Finally, relatively pure pyrophyllite from South Africa, or wonderstone, is used as a mold for artificial diamond production and in electric heaters and ceramics.

Product Grades and Specifications

To efficiently use pyrophyllite in industrial applications, it is necessary to identify and characterize all accompanying minerals and impurities. The different properties, grades, and specifications required for specific applications can be summarized as follows.

- **Refractory:** This requires an iron content of less than 1% and an absence of coarse quartz grains in the pyrophyllite ore. Fire resistance should exceed SK-30, and permanent expansion and good compaction on firing are necessary.
- **Pottery and tile:** For these applications, the siliceous pyrophyllite ore should have a high degree of whiteness and an iron content of less than 0.5%. In addition, high fire resistance, permanent expansion on firing, and low hydration expansion are required.

Table 7. Prices of pyrophyllite ores

Origin	Grade	Price Basis	Price, US\$/t	
			1996	October 2005
Australia	Filler grade, 300 mesh, milled	f.o.b. Sydney	230	342
South Korea	Ceramic grade, 15%–19% Al ₂ O ₃	f.o.b. Nohwado	27–44	27–44*
	Fiberglass grade, refractory grade, 18%–21% Al ₂ O ₃	f.o.b. Nohwado	59–65	59–65
	Clay filler grade, 21%–27% Al ₂ O ₃	f.o.b. Nohwado	110–150	110–150

Source: *Industrial Minerals* 1996, 2005.

* Minimal fluctuations in price over reporting period.

- **Cement:** This requires a pyrophyllite ore with low iron and alkaline contents and a high degree of whiteness after calcination.
- **Building materials:** A high degree of whiteness and a fine particle size are required for this application. Clays with high or low silica content are required for different products.
- **Glass fiber:** This requires clay with low iron, titanium, and alkaline contents, along with a fine particle size and high chemical stability and consistency.
- **Agricultural chemicals:** This grade of clay should contain stable particles and have high adherence and sticking tendencies. In general, it should have low specific gravity and moisture and be highly dispersible. A nearly neutral pH is required, as is stability over time when mixed with other chemicals.
- **Paper:** Pyrophyllite of this grade should have a high Al₂O₃ content, a low SiO₂ content, fine particles with no coarse elements, a stable particle distribution, and a high degree of whiteness.

In addition to the markets listed above, pyrophyllite ores and clay are also used in paint, plastics, colored aggregates, and medicines. The persistence of fine particles and chemical stability are valuable properties for most applications.

Prices

The price of pyrophyllite depends mainly on its Al₂O₃ content, although it is also affected by the presence of impurities such as iron and alkalis. Table 7 shows pyrophyllite prices in Australia and South Korea.

Competitive Substitutes

Chemical composition is of particular importance for ores used as raw materials in the manufacture of ceramics, cement, and long glass fibers. By contrast, physical properties—such as color, hardness, and particle size—are most significant for ores used in plastic fillers, paints, and construction materials. Stable pH value, particle size, and chemical composition are important for applications in pesticides and medicines. Although pyrophyllite was widely used as paper filler in the past, it has been largely replaced by soft kaolin, talc, and calcium carbonate in Japan.

INDUSTRY STRUCTURE AND ECONOMIC AND COMPETITIVE FACTORS

Infrastructure

In Japan, materials can be distributed by water, rail, and road. In recent years, motor vehicles have become the major form of trans-

portation because of advances in the maintenance of highways and the increasing demand for door-to-door services. Some observers, however, predict that rail transport in Japan, which was once considered a costly alternative, is becoming more competitive. Large port facilities allow a combination of sea and road transportation for the import and export of large consignments. South Korea has a complete network of water, rail, and road transport systems; however, because of the relatively small size, trucks are most commonly used. A main expressway system has been completed, and import and export ports are being constructed, although there are too few at present. In China, restricted water and road transport systems exist; however, international trade has rapidly expanded in recent years and a trade promotion policy has improved the transport infrastructure in urban areas and on the coast. In India, the railway and road haulage system—a result of the British heritage—is the major means of transport, and the infrastructure is continuing to improve, albeit slowly. The growth of coastal shipping systems and navigable waters in less developed countries invariably lags behind that of developed nations, and almost all ports and harbors in these countries fail to meet international standards.

Barriers to Entry

Strict rules and regulations concerning security, resources, and the environment, along with the enormous investment needed to develop a mine, make it difficult for newcomers to enter this industry. For example, in Japan, manufacturing commercial products for use in glass fibers requires highly specialized techniques for exploration, mining, grinding, and mixing; well-organized quality control; and accurate chemical analysis to produce good-quality pyrophyllite. In addition, customer requirements in the mining industry are often more demanding than those in other areas of commerce.

Economic Factors

The use of pyrophyllite in Japan has declined in recent years. At the same time, pyrophyllite production has become more difficult, manufacturing expenses have increased, and the price has decreased because of a lingering economic slump. Pyrophyllite bricks, once the mainstay of the refractory industry in Japan, have been almost entirely replaced by basic and high-alumina bricks. Low-grade bricks produced in China, where the manufacturing costs are lower, are being imported into Japan in increasing quantities. Similarly, in the tile industry, pyrophyllite consumption is decreasing and talc consumption is increasing, and the number of imported tiles is also growing. High-quality pyrophyllite powder for the manufacture of long glass fibers is increasingly being imported from South Korea and China; in addition, the costs of importing kaolin and silica clay into Japan have fallen recently, and these materials have begun to supplant pyrophyllite. In China, the production of refractories and glass fibers is rapidly expanding as a result of increased demand (Table 8).

Import Tariffs and Duties

The 2004 import tariffs on pyrophyllite ore in South Korea and Taiwan are 3.0% and 2.5%, respectively, and there are no import restrictions. Japan, Canada, and Australia do not impose import tariffs or restrictions on pyrophyllite, and the United States implements restrictions for only a few countries. In India, the breakdown of import duties is as follows: basic customs, 25%; special customs, 4%; and total customs, 30%. The import tariff in Brazil is about 5.5%, although the country has a complicated tax system and the tax ratios differ by state. China imposes an import tariff of 3.0% for selected countries such as South Korea, Japan, and the United

States, but the rate is 50% for all other nations; in addition, China emphasizes a protective trade policy.

By-Products

Most pyrophyllite containing high levels of iron and alkalis is discharged into waste piles or disposed of as unwanted stock. In Japan, some of this material is used in the production of eco-friendly goods and colored aggregates or in land reclamation. In other countries, including South Korea and China, the low-grade ores are partly used in eco-friendly goods, craft products, and road aggregates in the mining districts.

Depletion Allowance

Many countries, including the United States, Canada, Australia, and Europe, have a depletion allowance system to encourage mining, which recognizes that companies must continually acquire new mines and explore new prospects. Such allowances compensate companies for the loss of deposits or property, which gradually become depleted as the mines are operated. In Japan, there is no depletion-allowance system that resembles the ones in the United States and Europe, but the government allows mining companies either 12% of the sale proceeds from an ore or 50% of the income of a mining division to be reserved every year as a mine-prospecting reserve fund. This fund remains for 3 years and is then included in profits for taxation purposes. Pyrophyllite mining in Japan strictly follows this Japanese tax system.

Costs and Timing

Manufacturing expenses in the Japanese pyrophyllite industry have increased because of rising labor costs, investment in plants and equipment, resource conservation and environmental protection, and controls on dust produced during grinding. Regulations against overloading and exhaust control affect the costs of transportation. Despite increased manufacturing costs, the prices of most pyrophyllite products have declined in Japan. South Korea is also introducing stricter environmental regulations, although they are not as severe as those in Japan. In addition, the wages of workers in the mining industry are rising faster than wages in other sectors, leading to higher production costs. The prices of pyrophyllite products in South Korea are also increasing. Environmental regulations in China are less strict; however, it might be necessary to establish a reserve fund for the reclamation of mined land when mining rights are acquired. At present, China has comparatively little mechanization in rural areas, and most mining is performed by human power. China, however, is beginning to use modern equipment for crushing and grinding. Under the guidance of the government, improvements in the management of factors such as quality control, the maintenance of stable supplies, and safety issues in China are anticipated.

ENVIRONMENT

Safety, Health, and Environmental Sanitation

The stricter environmental regulations in Japan require greater efforts in the development of mines. In particular, safe working conditions during the mining, crushing, grinding, packing, and hauling processes are paramount. A company processing ore containing silica must use dust collectors, periodically measure the concentration of dust, and provide respirators for workers. In addition, periodic meetings about safety and health care are mandatory. Companies must recognize that managing the working environment is an important aspect of total quality control. Although these comments apply specifically to Japan, similar environmental requirements exist in several countries, albeit less stringent in some.

Land Use and Restriction

In general, facilities must be designed to minimize pollution, and mining is restricted in some instances because of potential contamination problems. The Japanese Mining Act allows companies to acquire a maximum of 350 ha of land per mine, with few exceptions. To prevent pollution at landfill sites (waste rock reclamation), mining companies must perform routine maintenance and analysis of groundwater and must keep records of the results.

Mined Land Reclamation

When open-pit or underground mining ends, mining companies must take measures to prevent pollution and improve the appearance of the mined land. For underground mining, acid water flow from the mine must be neutralized before the water can be discharged into nearby watercourses. To avoid this problem, levels and shafts should be filled in completely, and pitheads should then be sealed. With bench cuts, which are popular in open-pit mining, revegetation is required on the filled site or the berm of the mine to prevent the bedrock from sloughing and to stop muddy water from flowing outside the mine during rainfall. Vegetation also improves the appearance of mined land, and trees and plants that can be acclimated to the natural features of the locality should be chosen for this purpose.

Pollution Control

All the processes involved in the manufacture of pyrophyllite products, including mining, dressing, grinding, packing, and hauling, can pollute; therefore, preventive or protective measures must be implemented at each stage. Blasting in open-pit mining can cause vibrations and noise, and fly rocks may be thrown outside the area of the mine; these factors can cause serious problems for nearby residences or roads. Frequent blasts of small charges are preferable to large-scale blasting. Watering haul roads in the mine controls dust, and workers must wear respirators when in a dusty environment. Side ditches or sand sedimentation tanks are used to settle suspended materials before the water is released into local channels.

Dust control is particularly important during dressing, grinding, and packing. Although adequate procedures and the routine maintenance of dust collectors can prevent mineral dust from dispersing to some degree, workers must wear respirators to ensure that they are protected from inhaling dust.

Finally, precise combustion- and emission-control systems to collect noxious gases are necessary to prevent air pollution during the drying of pyrophyllite. Anti-pollution procedures should also include taking routine measurements in the working environment, as specified by law.

OUTLOOK AND FUTURE TRENDS

Pyrophyllite deposits are concentrated in East Asia, with South Korea, China, and Japan predicted to remain major producers. In

China, in particular, the consumption and production of refractories, cement, glass fibers, and ceramics should increase significantly as industry and the economy develop further. The domestic demand for glass fibers in China has shown a strong increase over recent years, and this is likely to continue in the future. Kaolin and silica sand, which are also used in glass fiber applications, are abundant in United States and Europe; if these materials could be mined inexpensively in East Asia, they might be used along with pyrophyllite as a raw material for glass fibers. Chinese pyrophyllite remains highly competitive, however, because of its quality and low price. Pyrophyllite is also used in various agricultural applications, although its consumption is declining in Japan because of the acreage reduction policy in agriculture.

The pyrophyllite output of Brazil has remained relatively constant. Despite unstable economic conditions, production levels could increase if the prices fall below those of similar-grade materials produced in the United States. Significant reserves of pyrophyllite exist in the Indian states of Uttar Pradesh and Madhya Pradesh. The major domestic uses of Indian pyrophyllite are in tiles and ceramics. Despite low labor costs, India has yet to become competitive in the international pyrophyllite market, mainly because of high internal transportation costs. The production of wonderstone is increasing in the Republic of South Africa. Furthermore, a large deposit of pyrophyllite containing iron sulfide was recently identified in the Russian Ural province; this deposit was evaluated for use in refractories and ceramics, and further research and development is expected. Additional deposits exist in the Sikhote Alin Area of Russia, and near Fangchenggang in the Guangxi region of China. The future of the pyrophyllite industry worldwide depends on the continued exploration and development of new deposits and on the development of new markets.

Rare Earth Elements

Stephen B. Castor and James B. Hedrick

INTRODUCTION

The rare earth elements (REEs), which include the 15 lanthanide elements ($Z = 57$ through 71) and yttrium ($Z = 39$), are so called because most of them were originally isolated in the 18th and 19th centuries as oxides from rare minerals. Because of their reactivity, the REEs were found to be difficult to refine to pure metal. Furthermore, efficient separation processes were not developed until the 20th century because of REEs' chemical similarity. A statement attributed to Sir William Crookes, a noted English scientist, betrays the frustrations of late 19th-century chemists with this group of elements (Emsley 2001):

The rare earth elements perplex us in our researches, baffle us in our speculations, and haunt us in our very dreams. They stretch like an unknown sea before us, mocking, mystifying and murmuring strange revelations and possibilities.

All of the REEs were finally identified in the 20th century. Promethium, the rarest, was not identified until 1945, and pure lutetium metal was not refined until 1953 (Emsley 2001). Commercial markets for most of the REEs have arisen in only the past 50 years.

Most REEs are not as uncommon in nature as the name implies. Cerium, the most abundant REE (Table 1), comprises more of the earth's crust than copper or lead. Many REEs are more common than tin and molybdenum, and all but promethium are more common than silver or mercury (Taylor and McLennan 1985).

Promethium, best known as an artificial element, occurs in very minute quantities in natural materials because it has no stable or long-lived isotopes. Lanthanide elements with low atomic numbers are generally more abundant in the earth's crust than those with high atomic numbers. Those with even atomic numbers are two to seven times more abundant than adjacent lanthanides with odd atomic numbers (Table 1).

The lanthanide elements traditionally have been divided into two groups: the light rare earth elements (LREEs)—lanthanum through europium ($Z = 57$ through 63); and the heavy rare earth elements (HREEs)—gadolinium through lutetium ($Z = 64$ through 71). Although yttrium is the lightest REE, it is usually grouped with the HREEs to which it is chemically and physically similar.

The REEs are lithophile elements (elements enriched in the earth's crust) that invariably occur together naturally because all are trivalent (except for Ce^{+4} and Eu^{+2} in some environments) and have

Table 1. REEs, atomic numbers, and abundances

Element	Symbol	Atomic Number	Upper Crust Abundance, ppm*	Chondrite Abundance, ppm†
Yttrium	Y	39	22	na‡

‡ na = not available.

similar ionic radii. An increase in atomic number in the lanthanide group is not accompanied by change in valence, and the lanthanide elements all inhabit the same cell in most versions of the periodic table. The similar radii and oxidation states of the REEs allow for liberal substitution of the REEs for each other into various crystal lattices. This substitution accounts for their wide dispersion in the earth's crust and the characteristic multiple occurrences of REEs within a single mineral. The chemical and physical differences that exist within the REEs group are caused by small differences in ionic radius and generally result in segregation of REEs into deposits enriched in either light lanthanides or heavy lanthanides plus yttrium.

The relative abundance of individual lanthanide elements has been found useful in the understanding of magmatic processes and natural aqueous systems. Comparisons are generally made using a

logarithmic plot of lanthanide abundances normalized to abundances in chondritic (ston y) mete orites. The use of this method eliminates the abundance variation between lanthanides of odd and even atomic number, and allows determination of the extent of fractionation between the lanthanides, because such fractionation is not considered to ha ve tak en place during chondrite formation. The method also is useful because chondrites are thought to be compositionally si milar to t he or iginal earth's mantle. Europium (Eu) anomalies (positive or negative departures of europium from chondrite-normalized plots) have been found to be particularly effective for petrogenetic modeling. In addition, REE isotopes, particularly of neodymium and samarium, have found use in petrogenetic modeling and geochronology.

HISTORY OF REE PRODUCTION

REEs wer e o riginally prod uced in min or amo unts from small deposits in gr anitic pegmatite, the geologic en vironment in which they were first discovered. During the second half of the 19th century and the first half of the 20th century, REEs came mainly from placer deposits, particularly t hose of the southeastern United States. With the exception of the most ab undant lanthanide elements (cerium, lanthanu m, and neodymium), in di vidual REEs were not commercia lly a vailable until the 1940s. Between 1965 and 1985, most of th e world's REEs came from Mountain Pass, California. Heavy mineral sands from placers in many parts of the world, however, were also sources o f b y-product REE minerals, and Australia was a major producer from such sources un til the early 1990s. Until recently, Russia also was an important REE producer from a hard rock source. During the 1980s, China emerged as a major producer of REE ra w materials, while the Austral ian and American market shares decreased dramatically (Figure 1). S ince 1998, more than 80% of the world's REE raw materials have come from China, and most of this production is from the Bayan Obo deposit in Inner Mongolia. Table 2 gives recent annual production figures by coun try, and Figure 2 sho ws locations of currently and recently productive REE mines.

MINERALS THAT CONTAIN REES

Although REEs comprise significant amounts of man y minerals, almost all production has come from less than 10 minerals. Table 3 lists those that have yielded REEs commercially or have potential for production in the future. Extraction from a potentially economic REE resource is strongly dependant on its REE mineralogy. In the past, producing deposits were limited to those co ntaining REE-bearing minerals that are relatively easy to concentrate because of coarse grain size or other attributes. Minerals that are easily broken down, such as the car bonate bastnasite, are mo re desirable than those that are difficult to dissociate, such as the silicate allanite. Placer monazite, once an importa nt source of REEs, has been largely abandoned because of its high thorium co ntent. Recently, REEs absorbed on clay minerals in laterite have become important sources of REEs in Chin a. For more information on REE-bearing minerals, see works by Mariano (1989a); and Jones, Wall, and Williams (1996).

GEOLOGY OF REE DEPOSITS

Iron-REE Deposits

Some iron deposits contain REE resources, and such deposits have been exploited in only one area—Bayan Obo, China. These deposits constitute the largest known REE resource in the world (Table 4) and are no w the most important REE source in the world (Haxel, Hedrick, and Orris 2002).

*"Other" includes India, Brazil, Kyrgyzstan, Sri Lanka, Russia, Malaysia, and Thailand.

Figure 1. Production of REEs by China, the United States, Australia, and other countries, 1983–2003

Iron-LREE-niobium deposits at Bayan Obo in Inner Mongolia, China, were discovered by Russian geologists in 1927 (Argall 1980) when Inner Mongolia was under the control of the former U.S.S.R. REEs are recovered from iron-REE-niobium (Fe-REE-Nb) ore bodies that ha ve been m ined from more than 20 sites since mining started in 1957 (Drew, Meng, and Sun 1990). The two largest are the Main and East ore bodies (Figure 3), each of which incl ude iron-REE resources with more than 1,000 m of strike length and average 5.41% and 5.18% rare earth oxides (REOs), respectively (Yuan et al. 1992). Total reserves have been reported as at least 1.5 b illion t of iron (average grade 35%), at leas t 48 Mt of REOs (a verage grade 6%), and ab out 1 Mt of niobium (average grade 0.13%) (Drew, Meng, and Sun 1990). The REE ore consists of three major types: REE-iron ore, the most important type; REE ore in silicate rock; and REE ore in dolomite (Yuan et al. 1992). Massive REE-iron ore occurs in 100-m-thick lenses with local banded and breccia structures. Banded and streaky fluorite-rich REE-iron ore has the highest REE content, locally more than 10 % REOs. Major oxide chemistries of several Bayan Obo ore types are shown in Table 5. REEs are mainly in bastnasite and monazite, but at least 20 other REE-bearing minerals ha ve been identified (Yuan et al. 1992). Bayan Obo ore has e xtreme LREE enrichment with no europium anomalies (Figure 4) and lo w strontium ($^{87}\text{Sr}/^{86}\text{Sr}$) (Nakai et al. 1989; Philpotts et al. 1989). Alkali-rich alteration (finitization), predominated by sodic amphibole and potash feldspar, is associated with the REE mineralization (Drew, Meng, and Sun 1990).

The Bayan Obo ore is hosted by dolomite of the Bayan Obo Group, a Middle Proterozoic clas tic and carbon ate sedimentary sequence (Qiu, Wang, and Zhao 1983; Chao et al. 1997) that occurs in an 18-km-long syncline (Drew, Meng, and Sun 1990). The Bayan Obo Group was deposited unconformably on 2.35-Ga migmatites, and, along with Carboniferous volcanics, was deformed during a Permian continent-to-continent collision event dominated by folding and thrusting (Drew, Meng, and Sun 1990). Intrusion of large amounts of Permian granitoid rocks also resulted from this collision.

The age of the REE mineralization is a matter of debate. It has been dated at 1600 Ma (Yuan et al. 1992) and 550 to 400 Ma (Chao et al. 1997). Most researchers agree that Fe-REE-Nb mineralization at Bay an Ob o took place over a long period of time.

* Source for mineral formulas: Mandarino 1999, with Ln = lanthanide elements.

† Sources for REO content: Frondel 1958; Overstreet 1967; Anon. 1980; Kapustin 1980; Mazzi and Munno 1983; Mariano 1989a.

‡ Where more than one analysis is available, the analysis with the highest REO content is reported (e.g., REO for monazite from the Mountain Pass carbonatite is reported; monazite from pegmatites and metamorphic rocks generally has lower REO).

§ Stoichiometric calculation of REO content.

Recent research points to ore formation during hydrothermal replacement of sedimentary dolomite, possibly related to one of the following:

- Alkaline or carbonatite magmatism (Drew, Meng, and Sun 1990; Campbell and Henderson 1997; Smith and Henderson 2000; Smith, Henderson, and Campbell 2000)
- Original emplacement of both the host dolomite and ore as igneous carbonatite with subsequent tectonic deformation (Le Bas, Spiro, and Yang 1997)
- Formation of host and ore by marine exhalation of alkalic or carbonatite-related fluids

Whatever its origin, the Bayan Obo deposits now dominate worldwide REE production and probably will do so for many years to come.

The Pea Ridge iron deposit in Missouri contains an undeveloped high-grade REE resource of unknown but probably small size in breccia pipes associated with 1.48-Ga granite and syenite (Kisvarsanyi, Sims, and Kisvarsanyi 1989). Bulk samples of REE-rich breccia, which contain monazite and xenotime, average about 12% REEs (Nuelle et al. 1992). Although the Pea Ridge resource is LREE-dominated, it also contains significant HREEs.

Mill tailings from processing magnetite deposits in Precambrian gabbro and syenite at Mineville, New York, are an REE resource of unknown size. They contain apatite that averages more than 11% REOs, including about 2% Y₂O₃ (McKeown and Klemic 1956).

The important magnetite and hematite deposits at Kiruna, Sweden, average 0.7% and 0.5% REOs, respectively, and other Swedish iron deposits contain similar amounts of REOs (Parak 1973). The REEs in these deposits are reportedly in apatite and monazite.

The huge Middle Proterozoic Olympic Dam copper-uranium-silver-gold deposit, South Australia, may also be included in this deposit type because most of the ore is breccia that contains 40% to 90% hematite along with quartz, sericite, fluorite, barite, sulfides, and REE minerals (Oreskes and Einaudi 1990). Olympic Dam is a potential source of by-product REEs, but typical content is about 0.5% total REEs, and there are no plans for REE production from the deposit. Extremely fine-grained monazite and bastnasite are the most abundant REE minerals, and the LREE/HREE ratio is high in Olympic Dam ore.

Carbonatite Deposits

Many carbonatite intrusions are enriched in REEs; Orris and Grauch (2002) list more than 100 carbonatite occurrences that contain REE minerals. Brief descriptions of REE mineral occurrences in carbonatites worldwide may be found in works by Mariano (1989a), Woolley (1987), and Wall and Mariano (1996).

Despite the abundance of REE-bearing carbonatites, REEs have been produced from only one, the Mountain Pass deposit in California. Although the Mountain Pass mine and plant did not operate in 2003, REE products were shipped from stockpile (Hedrick 2004a). Beginning in 1954, the Mountain Pass deposit was mined exclusively for REEs by Molycorp, Inc. (originally Molybdenum Corp. of America and now a subsidiary of Unocal). In 1987, proven and probable reserves totaled 29 Mt with an average grade of 8.9% REOs based on a 5% cutoff grade (Castor 1991). Current reserves are in excess of 20 Mt of ore at similar grade (Castor and Nason 2004). The ore typically contains 10% to 15% bastnasite, 65% calcite or dolomite, and 20% to 25% barite. Other gangue minerals, such as strontianite and talc, are present in significant amounts locally. Galena is locally abundant, but other sulfide minerals are rare. Bastnasite is the only mineral processed, although nine other REE minerals occur at Mountain Pass (Castor and Nason 2004). Mountain Pass ore has high LREEs and HREEs (Figure 4). The major oxide chemistry of Mountain Pass REE ore types is shown in Table 5.

The Mountain Pass carbonatite, which has been dated at about 1.4 Ga (DeWitt, Kwak, and Zartman 1987), is a moderately dipping, tabular intrusion (Figure 5) into granulite-grade gneiss. It is associated with ultrapotassic alkaline plutons of similar age, size, and orientation, as well as with abundant carbonatite and alkaline dikes, and is in a narrow north-trending zone of ultrapotassic alkaline igneous rocks at least 130 km long (Castor 1991; Castor and Nason 2004).

Elsewhere in the western United States, carbonatites have been investigated as possible sources of REEs, but none rival the Mountain Pass deposit as a REE resource. Similar to the Mountain

Table 4. Size and grade of some productive and potentially productive REE deposits

Pass carbonatite, most have high LREE/HREE ratios. The large Cambrian Iron Hill carbonatite in the Powderhorn District of Colorado has been considered a possible source of REEs, but Armbrustmacher (1980) reported a grade of about 0.5% REEs. Carbonatite dikes in the Powderhorn District that contain up to 3% REOs constitute a resource of unknown size (Olson and Hedlund 1981), and dikes in the nearby Wet Mountains constitute a small resource with a grade of about 2.5% REOs (Armbrustmacher 1988). Phanerozoic carbonatite dikes that contain as much as 21% REOs (Crowley 1960), mainly in monazite, allanite, and ancylite (Heinrich and Levinson 1961), are present in the North Fork Area on the Idaho–Montana border, but the size of this resource is probably small because dikes with high REO contents are generally less than 1 m thick.

Carbonatite complexes in eastern Canada also contain REE mineralization. A biotite-bearing carbonatite dike in Mesozoic carbonatite at Oka, Quebec, is an REE resource of unknown size and grade (Mariano 1989a). Bastnasite and monazite zones containing up to 4.5% LREEs have been identified in the Late Proterozoic St-Honore Complex in Quebec, with one 80-m drill intercept averaging more than 3% REOs (Vallee and Dubuc 1970).

Brazilian carbonatites contain significant REE resources but have yielded only minor production to date. Niobium ore in the Barreiro Complex at Araxá, Minas Gerais, which comprises 5450+ Mt averaging 2.5% Nb₂O₅, contains about 4.4% REOs (Issa Filho, Lima, and Souza 1984).

African carbonatites also contain LREE-dominated deposits that are largely unexploited. Kangankunde Hill, Malawi, is underlain by carbonatite dikes in which the main REE phase is monazite that is almost thorium-free (Garson 1966). The dikes are thought to contain a resource of several hundred thousand tons of monazite at an average grade of more than 5% (Deans 1966). Mariano (1989a) suggested that monazite in Kangankunde Hill carbonatite is of primary igneous origin like the bastnasite at Mountain Pass, but subsequent work indicated that the monazite, as well as associated bastnasite and florencite–goyazite, was formed from an original REE phase during hydrothermal activity (Wall and Mariano 1996). Carbonatite dikes at Wigu Hill, Tanzania, contain up to 20% REOs as monazite and REE fluorocarbonate minerals of possible hydrothermal origin (Deans 1966). The Palabora carbonatite in South Africa, which occurs in a large Early Proterozoic potassic alkaline complex, has significant copper and apatite production and has been evaluated as a source of REEs. Potential by-product from apatite

Adapted from Chao et al. 1997.

Figure 3. Geologic map of the Main and East iron-REE-niobium ore bodies at Bayan Obo, China

concentrates that contain 0.4% to 0.9% REOs has been estimated at 4,250 tpy (Notholt, Highley, and Deans 1990).

Sill-like lenses of bastnasite-fluorite-barite rock as much as 30 m thick with about 5% REEs are associated with carbonatite at Kizilçören, Turkey (Hatzl et al. 1990). The carbonatite occurs in dikes associated with intrusive Tertiary phonolites and trachytes along with alkaline pyroclastic rocks. The unexploited Kizilçören resource is dominantly LREEs (G. Morteani, personal communication).

Lateritic Deposits

Lateritic deposits that occur over low-grade primary sources, such as carbonatites and syenites, have been studied as potential REE sources since the 1980s. Such deposits may constitute large resources and some have high REE contents; however, only two deposits in China have been exploited to date.

REEs have been produced in increasing quantities in recent years from surficial clay deposits in southern China, and Orris and Grauch (2002) list 18 Chinese occurrences of such material. In 1992, REEs from these deposits comprised 14% of Chinese production (Wu, Yuan, and Bai 1996), and this source has had a strong impact on yttrium supplies since 1988. The deposits reportedly form weathering crusts over granite (Ren 1985; Wu,

Yuan, and Bai 1996). The ore, referred to as REE-bearing ionic absorption clay, mostly comes from two sites in Jiangxi Province—Longnan and Xunwu, the former yielding HREE- and yttrium-rich material and the other, LREE-rich material (O'Driscoll 2003). Ore from Longnan has an HREE-dominated

distribution pattern very similar to that of xenotime, whereas ore from Xunwu is relatively enriched in lanthanum (Hedrick 1992; Figure 6). Both ores have relatively low cerium content, suggesting deposition from REE-bearing groundwater with depleted cerium that results from the element's insolubility in the oxidized (Ce⁴⁺) state. The ore bodies are 3 to 10 m thick and occur mainly in a wholly weathered zone composed of halloysite and kaolinite with residual quartz and feldspar; grades are reported at 0.05% to 0.2% REOs (Wu, Yuan, and Bai 1996). The deposits are considered to be laterites and show similarities to a number of other lateritic deposits formed over alkaline igneous rocks and carbonatite (Morteani and Preinfalk 1996).

REE-enriched lateritic material overlying carbonatite is present in many sites worldwide, mostly in the tropics. Orris and Grauch (2002) list more than 50 such occurrences, but, other than the Chinese deposits, none have produced significant amounts of REEs.

The Mount Weld REE deposit in southern Western Australia is in the lateritized cap over a large carbonatite (Figure 7) dated at 2.0 Ga (Duncan and Willett 1990). Although LREE/HREE ratios are generally high, the laterite is locally enriched in HREEs and yttrium. Published reserve figures are 15.4 Mt with 11.2% REOs + Y₂O₃ (Mariano 1989a), and 2.3 Mt with 18.0% REOs (Willis 2002). Large volumes of ore contain an average of 0.33% Y₂O₃, and niobium and tantalum enrichment has also been reported (O'Driscoll 1988). Data from Lottnermoser (1990) indicate that unweathered carbonatite at depth contains 0.1% to 0.2% REOs. REE enrichment at Mount Weld is thought to have been caused by

long-term leaching and redeposition by groundwater; it mainly consists of REE phosphates (Mariano 1989a), including the yttrium-rich mineral churchite (Lottermoser 1988). During the formation of the weathered profile since Permian glaciation, LREEs were incorporated in phosphate and alumino-phosphate minerals in the upper part of the profile, and HREEs and Y were deposited as churchite at lower levels (Lottermoser 1990), leading to the formation of both LREE- and HREE-enriched ore (Figure 8). The Yangibana REE

prospect in northern Western Australia, a gossan containing as much as 11% REOs (O'Driscoll 1988), is thought to have been formed by weathering from a carbonatite associated with Early Proterozoic alkaline rocks.

The Araxá carbonatite complex in Brazil contains 800,000 t of supergene-enriched laterite that averages 13.5% REOs, mainly in the phosphate minerals gorceixite and goyazite (Mariano 1989a). In the Catalão I Complex about 300 km southeast of Araxá, phosphatic laterite comprises a resource of about 2 Mt averaging 12% REOs. The REEs are mainly in secondary phosphate minerals, such as gorceixite (Mariano 1989a; Morteau and Preinfalk 1996). Laterized carbonatite in the Maicuru Complex, Pará, northern Brazil, contains phosphatic material with as much as 17% REEs (Costa et al. 1991). Cerro Impacto, a large circular structure thought to be a deeply weathered carbonatite that is located in the Amazon region of Venezuela, contains as much as 11% REEs in thick laterite (O'Driscoll 1988).

Deeply weathered Brazilian carbonatites that contain large titanium resources in the form of a natase with associated REE phosphate minerals are also a potential source of by-product REEs

with high LREE/HREE ratios (Mariano 1989a). Titanium concentrates from a pilot plant contain more than 3% REEs that must be removed to produce commercial titania. Reserves are known to be substantial; the largest deposit, at Serra Negra, Minas Gerais, contains 200 Mt averaging 27.7% TiO_2 (Anon. 1984). Other poorly explored carbonatites in the Amazon region of South America are known to host supergene REE mineralization (Mariano 1989b).

REE-enriched laterites occur at 17 sites in Africa (Orris and Grauch 2002). The most thoroughly investigated deposit is probably monazite-rich laterite that includes 6 Mt of material with about 5% REOs that overlies carbonatite at Mrima Hill, Kenya. REE enrichment in the form of secondary hydroxylbastnasite and other minerals has been reported in karst-related lateritic deposits in Europe, such as upper Jurassic bauxite deposits in Montenegro (Maksimović and Pantó 1996).

Placer Deposits

Most placer accumulations with significant amounts of REE minerals are Tertiary or Quaternary deposits derived from source areas that include granitic rocks or high-grade metamorphic rocks; however, paleoplacer deposits that are as old as Precambrian contain REE resources. Orris and Grauch (2002) list more than 360 REE-bearing placers. Most commercial deposits are in sands of marine origin along or near present coastlines and consist of titanium mineral placers with by-product zircon and monazite; some contain xenotime. In the 1980s, monazite and xenotime from titania-zircon paleobeach placers in Australia were the third most important source of REEs in the world, but Australia currently exports little or no REE minerals from such sources, owing to their high thorium content.

Placer rutile-zircon-ilmenite deposits at Eneabba on Australia's west coast north of Perth, which produced about 2,500 t of monazite annually, were brought into production in the late 1970s. These deposits are still productive, but little or no monazite is currently marketed from them. Heavy minerals comprise about 6% of the sand mined at Eneabba, and monazite makes up 0.5% to 7.0% of the heavy minerals (Shepherd 1990). The heavy mineral sands lie 30 m or more above present sea level and were deposited in late Tertiary or early Pleistocene time (Lissiman and Oxenford 1975). Archean metamorphic rocks in the interior provided heavy minerals to Mesozoic sedimentary rocks that were reworked to form these deposits. In the Geographe Bay area near Capel, ilmenite-zircon paleobeach deposits that have been mined since the mid-1950s occur along a strike length of about 50 km in Pleistocene to Recent sands (Welch, Sofoulis, and Fitzgerald 1975). The setting and source are similar to those described for Eneabba. Although the average heavy mineral grade of Geographe Bay deposits is somewhat higher than at Eneabba, the monazite content of heavy mineral concentrates is lower, at 0.04% to 1.1% (Welch, Sofoulis, and Fitzgerald 1975).

Minor amounts of monazite were once produced from placers along Australia's east coast. Rutile and zircon are the main mineral products from these operations, which exploit Quaternary beach placers and sand dunes. Heavy mineral content in some of these deposits is less than 0.5% (Griffiths 1984), and monazite comprises less than 1% of the heavy mineral concentrate (McKellar 1975). The WIM 150 deposit, a placer in an interior basin in Victoria, contains large REE mineral resources. A 14-m-thick titanium and zirconium mineral sand deposit, underlies an extensive area amenable to dredging. Estimated REE mineral reserves exceed 580,000 t monazite and 170,000 t xenotime (O'Driscoll 1988).

In addition to Australia, by-product monazite has been extracted from beach deposits in Brazil, India, Malaysia, Thailand,

China, Taiwan, New Zealand, Sri Lanka, Indonesia, Zaire, Korea, and the United States. Present-day production is from India, Malaysia, Sri Lanka, Thailand, and Brazil. In India, monazite production from titania-zircon placers is government controlled, and a domestic plant processes monazite concentrate into REE products. In southeast Asia, monazite and xenotime are won from concentrates produced during placer tin, zircon, and titania mining. Prior to 1988, when China began to dominate yttrium production, xenotime from Malaysia was the largest source of yttrium in the world. Approximately 500 t of monazite per year were produced from 1952 to 1994 as a by-product of titania-zircon production from Pleistocene sands near Green Cove Springs in Florida.

Prior to large-scale exploitation of the Mountain Pass deposit, REE production in the United States came almost exclusively from nonmarine placers, although none comes from such sources now. The Carolina monazite belt, from which a total of about 5,000 t of monazite was produced between 1885 and 1917, has considerable placer reserves that average 0.25 kg/m³ of monazite (Overstreet 1967). In Idaho, REE minerals were produced in the 1950s from placers. Dredging operations near Cascade produced about 7,000 t of monazite from gravels containing about 1 kg/m³, and monazite reserves are estimated at 38,000 t (Overstreet 1967). Bear Valley, Idaho, where monazite and yttrium-bearing euxenite were mined by dredging, contains an estimated 10,000 t of REOs along with significant niobium and tantalum, on the basis of data from Kline et al. (1953). Some Idaho placers contain xenotime, particularly those in northern Idaho, and REEs are a possible by-product of placer gold mining in that area.

Metamorphosed Early Proterozoic conglomerate mined for uranium at Blind River, Ontario, Canada, contains REEs in monazite, uraninite, and brannerite (Roscoe 1969), and was the source of minor REE production from the 1950s to 1970s and again from 1986 to 1990. The heavy minerals in this ore are believed to be primarily of placer origin with possible enrichment during metamorphism or hydrothermal activity. Of the approximately 230 Mt of ore averaging 0.1% U_3O_8 estimated to be present in the district in 1973 (Robertson 1981), perhaps half remained unmined in the early 1990s, even though uranium mining didn't end until 1996.

At Music Valley in Southern California, xenotime- and monazite-rich zones with as much as 16% REOs (including 6% Y_2O_3) in Precambrian gneiss are thought to have originated as placer accumulations (Evans 1964). At Bald Mountain, Wyoming, a paleoplacer monazite resource was identified in Cambrian conglomerate (Borrowman and Rosenbaum 1962).

REE distribution plots of monazite and xenotime from most placer deposits have pronounced negative europium anomalies (Figure 9), indicating derivation from sources containing plagioclase. In addition, placer monazite has relatively high HREE contents compared with the strongly LREE-dominated hard-rock deposits at Bayan Obo and Mountain Pass.

HREE Deposits in Peralkaline Igneous Rocks

Although many REE deposits occur in peralkaline igneous rocks and resources can be large, most such deposits are relatively low grade, and only a single deposit in Russia has been mined. Peralkaline REE deposits are typically enriched in yttrium, HREEs, and zirconium. Future development of such deposits is dependent on the markets for these elements.

REE-bearing loparite has been produced for about 50 years from nepheline syenites in the peralkaline Paleozoic Lovozero massif on the Kola Peninsula in Russia. The massif is layered and is composed of four rock suites (Vlasov, Kuz'menko, and Yes'kova 1966). The upper 30% of the massif is eudialytic syenite.

The bottom, loparite-bearing section of the massif, over 1,000 m thick, comprises 65% of its volume and consists of alternating layers of nephelinites, nepheline syenites, and associated rocks. Late syenites occur as relatively small intrusions, and late mafic dikes are rare. The main rock-forming minerals are nepheline, microcline, and aegirine with accessory arfvedsonite, hydrosodalite, natrolite, and sodalite.

The loparite mostly occurs as 0.2- to 0.6-mm grains and rarely as larger crystals (Smirnov 1977; Vlasov, Kuz'menko, and Yes'kova 1966). Loparite contents are highest in areas of greatest differentiation and in rocks enriched in nepheline. It is found primarily in porphyritic rocks with concentrations in the urtites and their feldspar-aegirine equivalents, juvite, and malignite. The ore, in banded horizons from several centimeters to several meters thick, grades 2% to 3% loparite (Hedrick, Sinha, and Kosynkin 1997). The loparite contains 38.5% titanium oxide, 30% to 36% REOs, and 10% to 12% niobium and tantalum oxides. In the 1990s, 30,000 tpy of loparite were concentrated locally from ore from two mines and shipped to Estonia and Kazakhstan for processing (Kogarko et al. 1995). Loparite mining has ceased in recent years, but renewed production is being considered. The loparite REE distribution is weakly enriched in LREEs relative to HREEs (Figure 6).

During the 1980s when yttrium demand exceeded supply, exploration for yttrium-rich REE deposits led to the discovery of zirconium and HREE-dominated resources that are associated with peralkaline syenitic and granitic rocks. Some have associated beryllium, niobium, and tantalum. These resources are large but have low REE contents compared with commercial LREE-dominated deposits. Richardson and Birkett (1996) give an overview of Canadian peralkaline rock-associated deposits and compare them with similar deposits worldwide.

An HREE-zirconium deposit at Pajarito Mountain in New Mexico containing 2.4 Mt of rock with 0.18% Y_2O_3 and 1.2% ZrO_2 (Scherer 1990) consists of a 10-km² dome-shaped syenite intrusion (Kelley 1968). The main zirconium-REE phase was found to be eudialyte (Mariano 1989a).

Foliated syenite at Kipawa Lake, Ontario, includes a 1,300-by-100-m zone of yttrium- and zirconium-rich rock that contains eudialyte, mosandrite, and britholite (J. Allan, personal communication). The Y_2O_3 content of this deposit is comparable to that at Pajarito Mountain, but grade varies widely within the deposit, which was intensely deformed during the Grenville orogeny.

The Strange Lake zirconium-HREE-niobium-beryllium deposit in Quebec-Labrador is in a circular peralkaline granite complex about 6 km in diameter (Currie 1985). Reserves are reported at 5 Mt containing 0.5% yttrium and 3% zirconium along with beryllium, niobium, and tantalum credits (Miller 1988), and total reserves in the complex could be much larger. Most of the REEs are in gadolinite, bastnasite, and kinosite (A.N. Mariano, personal communication). Alkaline complexes in the Shallow Lake and Letitia Lake areas in Labrador, about 250 km southeast of Strange Lake, also include rocks with high yttrium content (Currie 1976; Miller 1988). Granite- and syenite-associated HREE resources with Y_2O_3 contents of about 0.2% have also been identified at Bokan Mountain in southeastern Alaska (Barker and Mardock 1988) and at Thor Lake in the Northwest Territories, Canada (Trueman et al. 1988; Taylor and Pollard 1996).

A Late Proterozoic peralkaline syenite complex at Ilmaussaq in southern Greenland contains layers with as much as 27% eudialyte (Ferguson 1970); the discovery of ore bodies containing 0.12% Y_2O_3 and 1.2% ZrO_2 has been reported (O'Driscoll 1988). The richest layer is 3.5 m thick and contains about 1 Mt of rock that

Figure 9. Chondrite-normalized plot of REE distribution (normalized to 100%) in placer monazite and xenotime (data source: Hedrick 1992)

averages 4% ZrO_2 (Steenfelt 1991). At Norra Kärr, Sweden, Middle Proterozoic eudialyte-bearing peralkaline syenite has been evaluated as a source of zirconium (Lundqvist 1980). Eudialyte from Norra Kärr contains 1.3% yttrium (Fryer and Edgar 1977).

Four Saudi Arabian deposits carrying REEs and zirconium occur in alkaline granites. The deposits include both LREE- and HREE-rich types, and estimated sizes range from 6 to 440 Mt with yttrium contents from 0.13% to 0.52% (Drysdaal et al. 1984). The Brockman deposit in northern Australia has been evaluated for zirconium, yttrium, HREEs, niobium, and tantalum. The deposit, in metamorphosed lower Proterozoic rhyolite tuff, consists of 9 Mt containing 1.3% zirconium, 0.15% Y_2O_3 , and 0.12% HREEs (O'Driscoll 1988). A deposit of altered Jurassic intrusive trachyte at Dubbo, New South Wales, Australia, is probably in this class. It contains 83 Mt with 1.9% zirconia, 0.14% Y_2O_3 , 0.12% REOs, and tantalum credits (Australian Zirconia Ltd. 2000). At Pocos de Caldas, Brazil, a Mesozoic or Early Tertiary peralkaline syenite complex 30 km in diameter (Woolley 1987) contains local concentrations of eudialyte. On the Kola Peninsula, Russia, Paleozoic peralkaline syenite complexes at Khibina and Lovozero contain large amounts of eudialyte-bearing rock (Gerasimovsky et al. 1974; Kogarko et al. 1995).

Vein Deposits

REE deposits in veins are typically small in comparison to the commercial hard-rock deposits at Bayan Obo and Mountain Pass. Nevertheless, REEs were produced from two vein deposits in Africa in the past, and more recently from two such deposits in China.

In recent years, Chinese vein deposits have become important REE sources. In 1992, production from the Maoniuping mine, Sichuan Province, and the Weishan mine, Shangdong Province, together accounted for 24% of Chinese REE production (Wu, Yuan, and Bai 1996). Both are described as bastnasite-barite-carbonate veins associated with quartz syenite. The y may be carbonatite dikes; published descriptions are not conclusive. The Maoniuping deposit, which is reportedly the second largest REE deposit in China (Pu, Chen, and Yang 2001), consists of swarms of veins and adjacent veinlets as much as 1,000 m long and 20 m wide that average about 2% REOs (Wu, Yuan, and Bai 1996). The ore mineral is coarse-grained bastnasite. Other REE minerals include chevkinite, xenotime, britholite, allanite, and monazite. Gangue minerals are barite, calcite, quartz, fluorite, feldspars, aegirine-augite,

and sulfide minerals. Ore at the Weishan mine occurs in veins as much as several hundred meters long and 1 m wide, with an average grade of 1.6% REOs. The mineral assemblage is similar to that at Maoniuping but also includes dolomite, amphiboles, thorite, titanium minerals, and niobium minerals (Wu, Yuan, and Bai 1996).

In South Africa, more than 50,000 t of monazite were produced in the 1950s and 1960s at Steenkampskraal (Neary and Highley 1984) from a monazite-apatite-quartz vein in Proterozoic granite. The vein, which occupies a shear zone, is about 300 m long and 1 m thick (Andreoli et al. 1994). Monazite comprises as much as 75% of the vein material (Overstreet 1967), accompanied by apatite, magnetite, and sulfide. The ore contains as much as 39% REOs with LREEs dominating HREEs and a pronounced negative europium anomaly (Andreoli et al. 1994). A similar monazite-apatite vein cuts Precambrian granite near Crescent Peak in Nevada about 30 km east of the Mountain Pass REE deposit (Castor 1991).

At Karonge, Burundi, in east Africa, quartz-barite-bastnasite-monazite stockwork veins that cut Precambrian quartzite and schist have produced small amounts of REEs (Notholt, Highley, and Deans 1990). The bastnasite and monazite have high LREEs typical of carbonates, but secondary cerianite and rhabdophane have abnormally high or low cerium contents because of oxidation (Van Wambeke 1977). In South Africa, small REE reserves have been estimated for britholite-bearing veins in the Pilanesberg peralkaline complex (Lurie 1986).

REE- and thorium-bearing quartz veins scattered over an area of about 250 km² at Lemhi Pass on the Idaho-Montana border in the United States comprise a REE resource of 370,000 t (Staatz, Sharp, and Hetland 1979). The mineralization is mostly LREE-dominated and averages less than 1% REOs, but some veins contain as much as 0.3% Y₂O₃ and 2.0% total REOs. A small area at Diamond Creek about 50 km northwest of Lemhi Pass contains veins with similar mineralogy but with low LREE/HREE ratios. The Snowbird occurrence in northwestern Montana is an REE resource of unknown size with 0.1% to 0.2% Y₂O₃. The REE minerals are in a Cretaceous quartz-carbonate-fluorite-parisite vein considered to be of hydrothermal origin (Metz et al. 1985). Thorite-bearing quartz-carbonate-fluorite veins at Hall Mountain near Port Hill in northernmost Idaho contain as much as 0.2% Y₂O₃. The Tertiary Bear Lodge trachyte-phonolite complex in Wyoming contains a minor REE resource in veins that average about 3% REOs (Staatz 1983), but the veins are narrow and commercial development is unlikely.

Veinlike deposits of apatite at Nolan's Bore, near Alice Springs in Australia, contain a significant amount of REEs. An inferred resource of 3.8 Mt of ore contains 4.0% REOs and 17% P₂O₅ (Anon. 2003). The REEs reportedly occur in the apatite and in REE minerals, with the latter possibly occurring as cross-cutting zones of cheralite.

Other Deposits

Some REE accumulations that do not fit into the deposit types previously discussed have had REE production or have been evaluated as possible sources. In recent years, a deposit near Aktyus in the Tien Shan Range of Kyrgyzstan has seen significant REE production. Although little information on this deposit exists in the literature, the deposit is said to contain complex ore from which lead, molybdenum, silver, and bismuth are also produced (Geological Survey of Kyrgyzstan 2004). The average REE content of the ore is reported to be 0.25%, with yttrium and HREEs making up 43.7% of the total REEs. The deposit consists of two stock-shaped bodies that contain synchisite-(Y), bastnasite, monazite, xenotime, and zircon (Roskill Information Services Ltd. 1996).

Some fluor spar deposits offer potential for REE production from associated REE minerals or from REEs that substitute for calcium in fluorite. Fluor spar mining at Naboomspruit in South Africa produced a small amount of monazite in the 1980s (Hedrick and Templeton 1991). About 65 t of bastnasite concentrate were produced from a fluor spar deposit in the Gallinas Mountains, New Mexico, in the 1950s (Adams 1965).

Near-economic HREE-uranium mineralization occurs as xenotime accumulations in sandstone of the Late Proterozoic Athabasca Group near Wheeler River in Alberta, Canada. Similar accumulations of HREEs and uranium are in quartzite in Western Australia (Mariano 1989a).

REE deposits in Vietnam are reported to contain several million tons with grades that range from 1.4% to 5% REOs with LREE- to moderate HREE-enriched distributions. The deposits have been described as crushed zones in Proterozoic limestone affected by metasomatic processes (Premoli 1989).

Marine phosphorites have been proposed as a potential source of REEs (Altschuler, Berman, and Cuttitta 1967). Certain members of the Permian Phosphoria Formation, which are mined for phosphate in large quantities in Montana and Idaho, contain significant amounts of REEs, including as much as 0.1% yttrium (Gulbrandsen 1966).

Pegmatite REE deposits are common but generally too small or too low in grade to be commercially exploited. Production of REEs from pegmatite mined for other minerals, such as feldspar or mica, however, is possible. Allanite-bearing pegmatites are relatively common, generally with high LREE/HREE ratios. In Australia's Northern Territory, a pegmatite deposit containing 1 Mt with 4% allanite was investigated as a source of REEs (O'Driscoll 1988).

ORIGIN OF DEPOSITS

The concentration and distribution of REEs in natural deposits are dependent on several petrogenetic processes, including enrichment and complexing in late-stage magmatic or hydrothermal fluids, fractionation into mineral phases, oxidation or reduction, and redistribution during weathering. LREE enrichment in igneous rocks generally is ascribed to fractionation of HREE into minerals such as garnet and pyroxene during partial melting of source materials or during fractional crystallization. In addition, an anomalously low europium/chondrite contents, a common feature in highly evolved igneous rocks of crustal derivation, are considered to be the result of Eu fractionation into plagioclase. Eu/Eu* (measured europium divided by europium calculated from interpolation between samarium and gadolinium; Henderson 1984) generally is near unity in mantle-derived rocks such as carbonatites but low in granitic rocks thought to have been derived by partial melting of crustal materials.

Lanthanum/gadolinium (La/Gd), as a measure of LREEs/HREEs, plotted against Eu/Eu* (Figure 10) is helpful in the classification of REE deposits and the interpretation of their origin. Whole rock and mineral plots for carbonatite REE deposits and laterite derived from carbonatite fall in a field of high La/Gd and Eu/Eu*. Carbonatites are considered to be mantle-derived rocks with little or no contribution from the crust. By comparison, monazite concentrates from Australian, Chinese, and Florida placer deposits plot in a tight cluster with high La/Gd and low Eu/Eu*, probably reflecting derivation from rocks that contained plagioclase or were produced by partial melting of plagioclase-bearing crustal rocks. HREE deposits in peralkaline rocks plot in a diffuse field with relatively low La/Gd and Eu/Eu*, probably because of derivation of the host peralkaline rocks from plagioclase-bearing crustal sources, and placer xenotime from Malaysia plots near the peralkaline field.

Some iron-REE deposits occupy a linear field that appears to connect the carbonatite and peralkaline HREE deposit fields, suggesting mixed crustal and mantle sources for the REEs, whereas ore from the Bayan Obo deposit plots within the carbonatite field, suggesting mantle derivation.

Most significant natural concentrations of REEs in nature are in, or associated with, alkaline igneous rocks and carbonatites. For deposits such as those at Mountain Pass, Mount Weld, Araxá, Pea Ridge, and Lovozero, this association is clear. At Bayan Obo, which emerged as the world's most important source of REEs in the 1990s, the association is less clear. Some researchers believe that the Bayan Obo deposits originated as carbonatite (Bai and Yuan 1985; Le Bas, Späth, and Yang 1997). Others believe that the deposit is hydrothermal, but call on an alkaline igneous or carbonatite source for the fluids (e.g., Drew, Meng, and Sun 1990; Yuan et al. 1992; Campbell and Henderson 1997). Still others call on mobilization of lower crustal REEs and deposition by hydrothermal activity during a protracted period of subduction (Chao et al. 1997). In addition, the Bayan Obo iron deposits have been compared to banded-iron formation deposits (Qiu, Wang, and Zhao 1983).

Hitzman, Oreskes, and Einaudi (1992) proposed a class of dominantly Proterozoic iron oxide (copper-uranium-gold-REE [Cu-U-Au-REE]) deposits that includes the Bayan Obo, Olympic Dam, Kiruna, and Pea Ridge deposits. They suggested that these deposits formed at relatively shallow crustal levels (< 4 to 6 km) from igneous-hydrothermal systems tapped by deep crustal structures associated with global rifting, possibly during break-up of a Proterozoic supercontinent. Hitzman, Oreskes, and Einaudi (1992) did not call for mantle or carbonatite-related fluids for this class of deposits, instead proposing release of large volumes of magmatic-hydrothermal fluid during magmatic underplating of the crust. By contrast, Chao et al. (1997) proposed a protracted Paleozoic lower crustal origin for REE-rich fluids at Bayan Obo on the basis of ages of amphiboles related to REE deposition. Smith (2001) noted evidence that the Olympic Dam deposit was formed from hypersaline brines and proposed that it should be placed in a separate category from Bayan Obo, which shows no evidence of such fluids.

The Mountain Pass deposit shares features with other carbonatites in the world: (1) textural and structural features that support igneous intrusive origin (Olson et al. 1954); (2) associated alkali-rich fenitic alteration; and (3) low $^{87}\text{Sr}/^{86}\text{Sr}$ (Powell, Hurley, and Fairbairn 1966; E. DeWitt, personal communication). But the shape of the carbonatite ore body, its ultrapotassic alkaline association (most carbonatites are associated with alkaline rocks that are dominantly sodic), and chemistry (it is unusually low in iron, phosphorus, and niobium for REE-rich carbonatite) suggest that its source was different than that of most other carbonatites (Castor and Nason 2004). The chemistry of the ultrapotassic alkaline rocks at Mountain Pass suggests that they were derived from primitive or depleted mantle mixed with an enriched mantle or crustal component, and the carbonatite likely came from a similar source. The Mountain Pass LREE deposit occurs in a northeasterly-trending belt of anorogenic Middle Proterozoic plutonism that crosses the North American continent (Anderson 1983) and contains eight Middle to Late Proterozoic REE deposits (Castor 1993, 1994).

Although there are mineral and chemical similarities between the Mountain Pass and Bayan Obo deposits, there are also major differences. Like the Bayan Obo ore, the Mountain Pass carbonatite ore has extreme LREE enrichment with no europium anomalies (Figure 4) and low $^{87}\text{Sr}/^{86}\text{Sr}$. As at Bayan Obo, alkali-rich alteration is associated with the Mountain Pass carbonatite; in both areas, alteration assemblages include sodic amphibole and potash feldspar

Location No.	Deposit Name and Type	Location No.	Deposit Name and Type
1A	Mountain Pass bastnasite	12	South China placer monazite
1B	Mountain Pass monazite	13	Florida placer monazite
2	Kangankunde REE-rich carbonatite	14	Brazil placer monazite

10, 11	Western and Eastern Australia placer monazite		

Figure 10. Plot of La/Gd against Eu/Eu* for some REE-rich mineral concentrate and rock samples (data sources: Deans 1966; Fryer and Edgar 1977; Qiu, Wang, and Zhao 1983; Drysdall et al. 1984; Hedrick 1985; Roeder et al. 1987; Barker and Mardock 1988; Nelson et al. 1988; Mariano 1989a; Costa et al. 1991; G. Morteani, personal communication; L. Tucker, personal communication)

(Olson et al. 1954; Drew, Meng, and Sun 1990). The Bayan Obo and Mountain Pass deposits are both enriched in barium and fluorine (Wu, Yuan, and Bai 1996; Castor and Nason 2004). Samples of Bayan Obo ore, however, have an average BaO content of about 2.4%, and a maximum barium content of 7.7% (based on data from Chao et al. 1997), much lower than Mountain Pass ore (Table 5). The fluorine content of Bayan Obo ore, which averages more than 9%, is much higher than that of Mountain Pass ore, and Bayan Obo ore also has higher phosphorus and niobium contents (Table 5). Deposits such as those at Bayan Obo, Pea Ridge, and Mineville are clearly different from Mountain Pass in their association with large amounts of iron. Whereas Mountain Pass ore contains about 10 times as much bastnasite as monazite, Bayan Obo deposits contain approximately equal amounts of bastnasite and monazite (Y. Qiu, personal communication), although bastnasite-rich ore is selectively mined. REE-chondrite patterns for Bayan Obo show enrichment in HREEs relative to Mountain Pass (Figure 4). Finally, the ultrapotassic alkaline intrusions that are associated with the Mountain Pass carbonatite are not found at Bayan Obo. On the basis of its relatively high P, Fe, and Nb contents, if the Bayan Obo deposit has a carbonatite-related origin, it is probably to a nepheline-carbonatite system rather than to an ultrapotassic-carbonatite system as at Mountain Pass.

The chemical compositions and mineral assemblages of most vein-type REE deposits suggest a genetic relationship with carbonatite-alkaline complexes. Such a relationship has been proposed for

the Karonge, Burundi, veins (Van Wambeke 1977). The monazite-apatite vein at Crescent Peak, Nevada, though, has REE distribution that includes a prominent negative europium anomaly that suggests a different origin than the Mountain Pass deposit 30 km away.

Although REE minerals are considered to be relatively unaffected by weathering, some lateritic REE deposits show signs of mobilization and redeposition of REEs. Residual concentration of REE minerals such as monazite is possible in laterite, and Morteani and Preinfalk (1996) reported that the REEs behaved as rather immobile elements in laterites at Araxá and Catalão in Brazil. Differences in REE distributions in different lateritic deposits may result from differences in parent rocks. For instance, Morteani and Preinfalk (1996) noted that REE distributions in the Araxá and Catalão laterites mirrored those in underlying alkaline rocks, and the very different REE distributions in the Xunwu and Longnan deposits in southern China (Figure 6) may be caused by different REE distributions in the parent rocks. As noted by Mariano (1989a), however, development of REE mineralization in laterites does not require derivation from independent REE minerals in the parent rock but may come from REEs in minerals that are less resistant to breaking down during weathering. Fractionation of the REE elements clearly takes place during weathering, as indicated by differences in REE distributions at different levels in the weathering cap above the Mount Weld carbonatite (Lottermoser 1990; Figure 8). The production of cerium anomalies (either positive or negative) during the breakdown of REE-bearing minerals in an oxygen-rich environment is to be expected; however, laterite deposits may or may not show such fractionation (compare Figure 8 with Figure 6). Mariano (1989b) proposed that differences in the mineral assemblages in carbonatite-derived laterites may result from factors other than parent rock composition, such as age, depth of weathering, and geomorphology.

TECHNOLOGY

Exploration Techniques

Geologic conditions favorable for REE deposits are widespread, but most of the world's hard-rock deposits are restricted to areas underlain by Precambrian rock. The Bayan Obo deposits, which are in Proterozoic rock, were originally discovered as ridge-forming surficial deposits of dark brown and black iron oxide (Argall 1980). Carbonatite REE deposits and many HREE deposits occur in or are associated with alkaline rocks in circular complexes, generally in Precambrian host rocks. Such complexes may be identified using aerial photography, even in deeply weathered and highly vegetated areas. Although isolated alkaline-carbonatite complexes such as Mount Weld in Australia do occur, most are in clusters or linear belts like those associated with rift zones in eastern Africa and the Araxá-Catalão belt in Brazil.

Sources for placer REE deposits include granitic rocks or high-grade metamorphic rocks, or both. Coastal monazite-bearing placers in Western Australia, Brazil, India, Sri Lanka, and the southeastern United States were derived from highly metamorphosed Precambrian shield rocks; whereas monazite and xenotime-producing placers in Eastern Australia, Malaysia, Indonesia, China, and Korea were eroded from Phanerozoic granites, including tin-rich granites. Sources of monazite, euxenite, and xenotime in Idaho placers include both highly metamorphosed Precambrian rocks and Mesozoic granitic rocks.

Because REEs are associated with thorium and uranium, radiometric exploration techniques are extremely useful in REE exploration. REE-rich carbonatite at Mountain Pass was discovered during surface prospecting for uranium using a geiger counter (Olson et al. 1954). Many other REE deposits were found by surface or airborne radiometric surveying. Although most placer REE

deposits yield only subtle radiometric signatures, careful data collection and analysis can be used to locate favorable intrabasin areas or horizons.

Geochemical prospecting using heavy-mineral concentration of active stream sediments can be very effective because most REE minerals are relatively heavy and resistant. Concentrates made by hand panning, mechanized gravity concentration, or heavy media separation can be analyzed for REEs using inexpensive multielement analytical techniques. Because many REE minerals are resistant to chemical breakdown, use of analytical methods that do not require dissolution, such as x-ray fluorescence or neutron activation analysis, is desirable, or care must be taken to use methods that assure total dissolution when using a technique such as inductively coupled plasma (ICP) spectroscopy. During prospecting for REE placer deposits in Idaho, the senior author found that favorable basins yield heavy-mineral concentrates with 1% or more cerium and 0.1% or more yttrium. Splittings of heavy-mineral concentrates taken during exploration should be saved so mineral determinations can be performed using microscopic or other techniques.

Regional geochemical surveys can be used to find igneous rocks that are likely to host or be associated with REE deposits. Carbonatite deposits were delineated in Greenland using multielement analysis of fine stream sediment samples collected at a density of 1 sample/30 km² (Steenfelt 1991). The Magnet Cove alkaline-carbonatite complex in Arkansas was delineated using REEs, titanium, and fluorine contents of stream silt samples collected at a density of 1 sample/10 km² (Sadeghi and Steele 1989). Peralkaline rocks that host HREE deposits in Greenland were delineated using niobium content in fine stream sediments collected at 1 sample/6.25 km² (Steenfelt 1991). The Strange Lake deposit in Canada was discovered using regional lake water and sediment surveys, with subsequent tracing of glacially transported boulders that were initially recognized 20 km from their source (Richardson and Birkett 1996).

Biogeochemical prospecting may be useful in defining buried REE targets. REE contents of plant ash have been analyzed in areas that contain pegmatitic and vein occurrences in Finland and Canada, and extreme LREE enrichment has been noted in plant ash from the Bayan Obo area (Dunn 1995).

Normal surface exploration techniques, such as trenching and pitting by heavy equipment, are used to evaluate poorly exposed REE deposits. Exploratory dredging is used to locate beach placer deposits. In countries with low labor costs, hand pitting may be used to evaluate placer deposits or unconsolidated deposits such as those in laterite.

Drilling techniques utilized for hard-rock REE exploration and prospect evaluation are mainly core drilling and dual-tube rotary or hammer drilling. The method of choice for most heavy-mineral placer evaluations is dual-tube rotary drilling. The collection of large samples, such as are necessary to evaluate gold placers, generally is not needed because the nugget effect is not a factor in most heavy-mineral sands that contain REEs.

Because of the economic importance of differences in processing REE-bearing minerals, identification of the REE-bearing phases in prospective deposits is important. Light-colored REE minerals, such as bastnaesite and monazite, may generally be distinguished by a green luminescence when illuminated by a mercury vapor light (Murata and Bastron 1956). A conventional black light with the purple filter removed may be used for this test. This luminescence, which is caused by absorption and indicates the presence of significant amounts of neodymium, has been used successfully for preliminary REE-grade determination during core logging at Mountain Pass. Because the test is based on neodymium content,

HREE minerals may not respond. Absorption bands in the visible spectrum may also be used to distinguish REE minerals with the aid of a hand spectroscope (Mertie 1960).

Geophysical methods that can be used to search for buried iron-REE deposits and some REE carbonatite deposits include gravity surveys and airborne or surface magnetic surveys. The effectiveness of such methods is based on anomalous density and magnetic susceptibility of a deposit and the associated rocks. Because many carbonate complexes have a central carbonatite mass surrounded by mafic alkaline rocks, a common signature is a magnetic bull's-eye with high central values combined with a centrally located gravity low and a concentric gravity high. The Mountain Pass carbonatite, however, does not follow this pattern because of its high density (caused by abundant barite and bastnaesite) and lack of magnetite. The Mount Weld carbonatite was discovered during interpretation of a regional aeromagnetic survey, and its detailed magnetic expression exhibits concentric zoning (Gunn and Dentith 1997). Other geophysical techniques include seismic surveys, which may be used in conjunction with drilling to determine the depth to bedrock of placer deposits.

Mining

At Mountain Pass, REE ore was mined until October 2001 in an open pit approximately 150 m deep using 80-t haul trucks and a 10-m³ shovel. Blast holes drilled at 3 to 4 m spacing were assayed for total REOs and other elements by x-ray fluorescence methods. Approximately 300,000 tpy were mined with a stripping ratio of 5:1 or higher. The ore was crushed using jaw and impact crushers at the upper lip of the pit and fed to an adjacent mill. Mining operations may be restarted in 2006 following governmental approval for pit expansion and a new tailings disposal site; however, newly enacted California mining regulations could block the resumption of mining.

At Bayan Obo, iron and REE ore is mined from two large open pits at a rate of at least 15,000 tpd using electric shovels and rail haulage (Argall 1980). Because water is lacking near the mine, crushed ore is hauled about 150 km by railroad to milling facilities at Baotou. According to Argall (1980), there was no selective mining at Bayan Obo to maximize production of any group of minerals. Originally, REO minerals may have been recovered from iron ore waste. According to Jackson and Christiansen (1993), however, REO in the iron ore is locked in slag during refining and is not recovered, and REO is produced strictly from bastnaesite ore that occurs in certain zones. According to L. Drew (personal communication), during the late 1980s, REE ore came from areas mined specifically for REE production, although iron ore and REE ore were hauled on the same trains to Baotou, where most cars were routed to steel mills and some to nearby REE processing facilities. During the 1990s, REE ore enrichment by hand cobbing was witnessed at the mining operation.

Russia's loparite was mined as a primary product by underground and open-pit methods from ore bodies in the Lovozero alkali massif near the city of Revda. The mining company, Lovozersky GOK, has plans to reopen and expand its mining capacity to 2.6 Mtpy of ore; however, problems with downstream processing of loparite concentrate in Estonia probably precludes expansion in the near future.

REE placer mining is done by either dry land mining or by dredging techniques. Although Australia does not currently export monazite from titanite and zircon placer operations, descriptions of the placer mining operations in that country are probably representative of placer mining that yields monazite and xenotime elsewhere. Dredges with capacities of as much as 2,800 tpy (Anon.

1987) were used in the 1980s to mine beach and dune sand deposits, particularly along the east coast. Dry land techniques, including loader and truck, scraper, drag line, or bucket wheel mining, are used for most of the heavy mineral sand mining in Western Australia (Griffiths 1984).

Processing

Flotation was used at Mountain Pass to make a bastnaesite concentrate containing about 60% REOs until late in 2001. Figure 11 is a simplified flow chart for concentrate production at Mountain Pass. This concentrate was used either (1) on site as feed for chemical separation of REEs; (2) leached with dilute HCl to produce a 70% REO concentrate; or (3) shipped as is. Current sales are from stockpile. Flotation that produces concentrate containing about 60% REOs is used at Baotou to process REE ore from the Bayan Obo deposit. In Russia, loparite ore was processed using gravity and electromagnetic separation methods to produce a 95% loparite concentrate. The mill has the capacity to produce about 6,500 t of contained REOs in loparite concentrate annually, and an expansion to 12,500 t of capacity is planned.

REE minerals are separated commercially from associated minerals in placer deposits using a combination of gravity, magnetic, and electrostatic techniques (Griffiths 1984). Figure 12 is a typical beneficiation flow diagram for monazite and xenotime. Gravity methods include the use of jigs, spiral and cone concentrators, and shaking tables. Sizing and preconcentration commonly is performed at the mine site by trommels, shaking screens, and gravity separation. Many dredges have such facilities on board or utilize floating preconcentration plants.

REE extraction from monazite and xenotime is accomplished by dissolution in hot concentrated base or acid solutions. During past processing of monazite ore, REEs were extracted using a concentrated solution of sodium hydroxide at 140 ° to 150 °C (Kaczmarek 1980). After cooling, hydroxides of REEs and thorium were recovered by filtration, and thorium was separated by dissolution and selective precipitation. Monazite and xenotime also have been processed using hot sulfuric acid digestion and water leaching to remove phosphate. This is followed by selective precipitation of thorium during dilution and precipitation of REEs as double sulfates.

At Mountain Pass, bastnaesite was calcined to drive off CO₂ and fluorine and leached with HCl to dissolve most of the trivalent REEs (Figure 11). The residue, which consists mostly of CeO₂, was sold as a polishing abrasive. At Baotou, Bayan Obo REE mineral concentrate is baked with sulfuric acid at 300 °C to 600 °C and leached with water, taking REEs into solution and precipitating other elements as waste (Chegwidden and Kingsnorth 2002). REEs are then precipitated as double sulfates and converted to hydroxides, which are leached with HCl for purification using solvent extraction (SX) and other methods. Because this method is very similar to placer monazite processing, the Bayan Obo concentrate is assumed to contain significant amounts of monazite.

Russian loparite concentrate is produced by a mill with the capacity to generate about 6,500 tpy. The concentration process uses gravity and electromagnetic separation methods, and yields a concentrate containing 95% loparite. The mill also produces aegirine and nepheline-feldspar concentrates. If mining expansion plans move forward, expansion of the mill will produce 3,000 t of loparite concentrate in a pilot phase followed by 12,500 t in the commercial phase. Additional expansion, if warranted, would increase loparite concentrate capacity to 25,000 tpy.

Russian loparite concentrate is processed using gaseous chlorination at high temperature in the presence of reducing agents

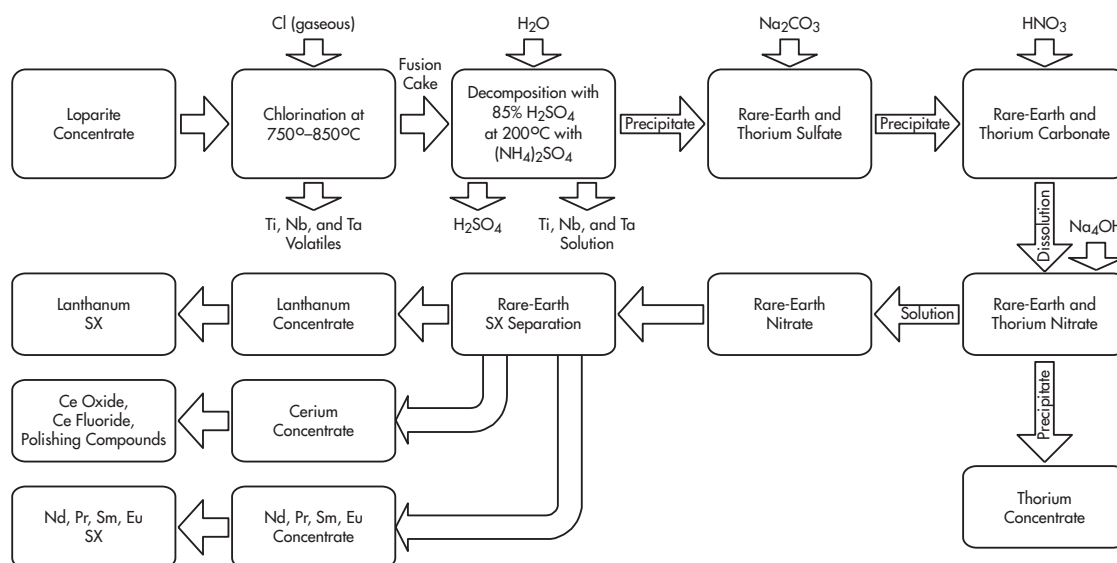

Figure 13. Loparite refinery flow diagram (Irtys, East Kazakhstan Oblast, Kazakhstan, and Sillamjõe, Estonia)

(Mikhailichenko, Mikhlin, and Pattrikeev 1987). The more volatile chlorides of titanium, niobium, and tantalum are separated from the less volatile chlorides of REEs and other elements, which remain as a fusion cake (Figure 13). The fusion cake is dissolved in hot sulfuric acid in the presence of ammonium sulfate (Kosynkin et al. 1993). The solution is diluted with water, dropping out double sulfates of rare earths and thorium that are converted to carbonates by the addition of sodium carbonate. The carbonate is dissolved in nitric acid, and thorium is precipitated by raising solution alkalinity (Hedrick and Sinha 1994) or by solvent extraction. The remaining rare earth nitrate solution is separated and purified by selective precipitation and solvent extraction.

Because of their chemical similarity, the trivalent REEs are difficult to separate. Although fractional crystallization and ion-exchange techniques are used to separate them in small amounts, commercial separation generally is done using liquid-liquid solvent extraction (Kaczmarek 1980). This process consists of addition of a solvent composed of a mixture of organic compounds to the pregnant aqueous solution in a series of mixing/settling cells that allow repetitive fractionation during a more-or-less continuously flowing process. Figure 14 is a simplified diagram of the SX process used at Mountain Pass. Following precipitation and drying, specific REE compounds with purities in excess of 99.99% can be produced by this process. At Mountain Pass, a REE fraction produced during SX was treated to separate europium by reduction to the divalent state, with ultimate purification as europium oxalate (D. Witham, personal communication). Other individual REE compounds were precipitated as hydroxides, carbonates, and oxalates following complex iterative SX processes.

Specifications and Testing

Specifications for REE mineral concentrates, compounds, and metals vary depending on use. Purity specifications for some compounds may be determined by reference to Table 6. Testing of REE products mainly consists of purity determinations. In addition to specific wet chemical analytical procedures, the most effective techniques used to test products for individual REE content are x-ray fluorescence, ICP emission spectroscopy, and instrumental

neutron activation analyses. Impurities, such as phosphate, silica, lead, and thorium, may be deleterious to product utilization or the environment. The need to limit such impurities depends on use. Physical specifications, such as particle-size distribution, color, and moisture content, also are important for some products.

Advances in processing in recent years have removed markets for some relatively low-spec REE products. For instance, a 90% cerium oxide product used mainly by the glass industry and manufactured cheaply for years at Mountain Pass has been supplanted by higher-grade cerium products with little or no price increase.

ECONOMIC FACTORS

Prices

REE mineral concentrates and intermediate compounds had relatively steady price and production increases from the 1960s through the 1980s, when markets were created in response to new technologies (Castor 1994), while REE sources remained relatively steady. In recent years, prices for REE concentrates and intermediate compounds can be considered expensive when compared with many other mineral products (Table 6) and have lagged behind inflation. REE production increases accelerated following significant Chinese impact on the market in the 1990s (Figure 1), while prices for all REE commodities have decreased (Table 7). Therefore, despite a total annual production increase on the order of 300% since the early 1980s, the overall dollar value of the REE market has probably remained static or even decreased.

Prices for individual REOs and metals were generally lower in the late 1990s and early 2000s than in the 1960s, 1970s, and 1980s. Individual REE compounds vary widely in value (Table 7), mostly because of relative abundance and production costs. The most expensive REE is the heaviest—lutetium, which sold as the high-purity oxide for as much as \$9,000/kg in 1989 (Hedrick 1991a) and declined to a low of \$2,400/kg in 2003. Metallic REEs typically have higher prices than their equivalent oxides or other compounds. Mischmetal, a mixture of metallic REEs, was quoted at \$12.35/kg at the end of 1989 (Hedrick 1991a). During the 1980s, individual REE prices generally were static or increased slightly, but, since then, market changes have caused price decreases for individual

Table 8. REE uses and applications by industry

Automotive	Catalysts for pollution control; catalytic converter catalyst substrate; rechargeable batteries; fuel cells; colored plastics
Ceramics	Oxygen sensors; structural ceramics for bearings; jet engine coatings; investment molds; refractories; pigments
Chemicals	Oil refinery fluid cracking catalysts; pharmaceuticals; water treatment; catalysts; moisture control, dryers, and detection
Defense	Lasers; missile guidance and control; visual displays; radar; electronic countermeasures; communication; shielding
Electronics	Capacitors; cathodes; electrodes; semiconductors; thermistors; traveling wave tubes (TWTs); radio frequency circulators and toroids; yttrium iron garnet (YIG) ferrites
Glass	Polishing compounds; decolorizing; coloring; increase refraction; decrease dispersion; radiation stabilization; absorber
Illumination	Trichromatic fluorescent lamps; mercury lamps; carbon arc lamps; gas mantles; auto headlamps; long-glow phosphors
Magnets	Speakers and headphones; linear motors; antilock braking systems; tape and disk drives; gauges; electric motors; pumps; ignition
Magnetostrictive	Sonar systems; precise actuators; precision positioning; vibratory screens; speakers; ultrasonics to kill bacteria
Medical	Contrast agents; magnetic resonance imaging (MRI); positron emission tomography (PET); radioisotope tracers and emitters
Metallurgy	Alloying agents in aluminum, magnesium, iron, nickel, and steel alloys; superalloys; pyrophoric alloys; lighter flints; armaments
Phosphors	Cathode-ray tubes (CRTs); fluorescent lighting; radar and cockpit displays; x-ray intensifying screens; temperature sensors
Other	Simulated gemstones; textiles; magnetic refrigeration; hydrogen fuel storage; lubrication; photography; nuclear uses

REE commodities. Samarium oxide, for which demand often exceeded supply during the late 1980s, sold for \$187/kg in 1988 but currently is available at \$58/kg because neodymium-iron-boron magnets have supplanted much of its market share. Europium oxide also has decreased in price from about \$2,000/kg in 1980 to \$1,120/kg in 2003. REE prices are generally lower for metric-ton quantities or long-term contracts.

Yttrium raw materials varied greatly in price during the 1980s, selling for as much as \$50/kg for contained Y₂O₃ in a 60% concentrate in the mid-1980s, retreating to \$32/kg by 1989. In the 1990s, yttrium-enriched ion-adsorption lateritic clays from southern China began supplying increasing amounts of low-cost yttrium oxide, significantly reducing demand for other yttrium concentrates derived from monazite and xenotime. The availability of low-cost yttrium oxide (\$7 to \$10/kg in metric-ton quantities in 2003) has essentially eliminated the competition in yttrium concentrate.

Rare Earth Uses and Markets

REEs are used in a wide variety of applications (Table 8). Comprising one of the widest ranges of consumer products of any element group, their usage is believed to be a significant economic indicator. Traditional REE applications in lighter flints, carbon arc lighting, and iron and steel additives have declined from 75% of the overall international REE market in the 1950s to about 20% in the 2000s.

Figure 15. Rare earth markets by weight

Uses in glass polishing and ceramics are the largest market for REE commodities by weight (Figure 15). Substantial amounts of cerium concentrates and cerium oxide are used in glass-polishing applications. The automotive catalyst industry also consumes significant REEs by weight, using cerium carbonate and cerium oxide in the catalyst substrate and as a component of the converter's oxidizing catalyst system. During the 1980s, REE production increases resulted from the rising use of cerium in automotive catalytic converters (O'Driscoll 1988). The use of lanthanum-rich mixed REE compounds in fluid cracking catalysts (FCCs) in petroleum refining also has been a major market (Figure 15). Although this application initially declined substantially in the mid-1980s when legislation mandated the use of unleaded fuels, the yield of gasoline and other light-fraction products was so reduced that consumption of REE-containing FCCs were restored. Phosphors, electronics, and laser crystals provide relatively minor markets by weight, although most are high value.

Although it only comprises 3% of REE production by weight, the phosphor market is probably the most important in terms of dollar value. Beginning in the 1960s, color television manufacturers spurred demand for high-value REE phosphors based on yttrium and europium; later, gadolinium and terbium compounds were added as phosphors. More recently, their use in trichromatic phosphors in fluorescent lighting resulted in increased production.

The introduction of high-strength samarium-cobalt permanent magnets developed by Karl Strnat in the 1970s, particularly for use in small electric motors and headphones, created a dynamic new REE market. Although higher-strength, lower-cost neodymium-iron-boron permanent magnets are now substituted for the more expensive samarium-cobalt magnets in most applications, samarium-cobalt magnets are still used in applications requiring higher temperatures.

Proposed new uses have increased a awareness of potential profits in REE raw materials. Superconducting substances containing lanthanum or yttrium have been in the spotlight since 1986. Volume markets for these substances, however, await further technological breakthroughs. New methods have been devised for REEs used in hydrogen-based refrigeration and energy storage. Market expansion for yttrium has provided an incentive for increased production from HREE deposits. In addition to its use in television, computer, and lighting phosphors, yttrium has found increased use in stabilized-zirconia ceramics applied in structural parts, bearings,

oxygen sensors, simulated gemstones, golf clubs and shoe cleats, shirt buttons, and coatings in the exhaust section of jet engines.

Although worldwide demand for REEs has had a general upward trend for many decades, REEs' economics are as complex as their chemistry. Because individual REEs occur together in most deposits in fixed ratios, the economic riddle is how to balance production against market demand. To accomplish this, each REE must be assigned a factor based on its natural abundance in the ore mineral in order to develop marketing equations, such as determination of price. Complexity of these equations are enhanced by variations in separation and purification costs between the REEs. In addition, markets for individual REEs may change rapidly because of technological changes and other factors. Marketing variability may also lead to stockpiling of unmarketable REE fractions and products by producers.

The principal source of REE ores is China, with smaller amounts available from India, Kazakhstan, Kyrgyzstan, Malaysia, Russia, Thailand, and the United States. Refined rare earth products, including compounds, metals, and alloys, are primarily produced in China and France.

U.S. imports were dominated by Chinese material in 2003, with 75% of domestic imports, by weight. France, with 10%, was the next largest source of U.S. imports (down from 30% in 2000), and Japan was third, with 4%. France and Japan, however, do not mine REEs and source the majority of their supplies from China. Therefore, the amount of Chinese REEs that the United States actually imported in 2003 was probably 89%. For the rare earth trade categories of domestic imports, the percentage of shipments supplied by China, by weight, were as follows:

- Cerium compounds: 84%
- Yttrium compounds: 63%
- Individual REE compounds (except cerium): 64%
- Mixtures of REOs (except cerium): 97%
- REE metals (intermixed or interalloyed): 73%
- Mixtures of REE chlorides: 94%

China was the leading source of materials for all rare earth import categories except ferrocerium and other pyrophoric alloys, a small volume trade category supplied mainly from France, at 82% of the import market.

In the mid-1980s, U.S. imports exhibited a very different distribution, at lower quantities because of high REE production from Mountain Pass. The leading supplier of domestic imports in 1985 in each category by percentage of shipments by weight, were as follows:

- Cerium compounds (except oxide): France, 89%
- Cerium oxide: France, 98%
- Individual REOs (excluding cerium): France, 84%
- REE alloys (including mischmetal): Brazil, 87%
- REE metals: former U.S.S.R., 65%
- Other REE metals: Federal Republic of Germany, 21%
- Ferrocerium and other pyrophoric alloys: France, 59%

In 1985, the majority of rare earth imports came from France, at 48%, with China supplying only about 1%.

Domestic production trended upward from the 1960s, when bastnasite production from Mountain Pass became commercially available, to the 1990s. Concentrate production at Mountain Pass ceased during 2001, when the mine and mill were put on standby status. Stocks of bastnasite concentrates and some REE intermediate and purified compounds are available from stockpiles, however.

Table 9. Harmonized Tariff Schedule for rare earth commodities imported into the United States in 2004

Heading/ Subheading Codes	Article Description	Normal Trade Relations	Non-normal Trade Relations	Special Program Codes*
2530.90.8050	Mineral substances not elsewhere specified or included; rare earth metal ores, e.g., xenotime (complex phosphate) and gadolinite, ytterbite, and cerite (complex silicates)	Free	0.3¢/kg	
2612.20.0000	Thorium ores and concentrates; rare earth metal ores, e.g., monazite (thorium and rare earth phosphate)	Free	Free	
2805.30.0000	Rare earth metals, including scandium and yttrium, whether intermixed or interalloyed, ad valorem	5.0% ad valorem	31.3% ad valorem	Free A+, CA, CL, D, E, IL J, JO, MX, 3.7% (SG)
2846.10.0000	Cerium compounds, including oxides, carbonates, hydroxides, nitrates, sulfates, chlorides, oxalates, and so forth	5.5% ad valorem	35% ad valorem	Free A, CA, CL, E, IL, J, JO, MX, 4.1% (SG)
2846.90.2010	Mixtures of rare earth oxides, including yttrium and scandium, other than cerium oxides	Free	25% ad valorem	
2846.90.2050	Mixtures of rare earth chlorides, except cerium chloride	Free	25% ad valorem	
2846.90.4000	Yttrium-bearing materials and compounds containing by weight >19% but <85% yttrium oxide equivalent	Free	25% ad valorem	
2846.90.8000	Rare earth compounds, including individual REOs, rare earth hydroxide, rare earth nitrate, and other compounds (excludes cerium compounds, mixtures of REOs, and mixtures of rare earth chlorides)	3.7% ad valorem	25% ad valorem	Free A, CA, CL, E, IL, J, JO, K, MX, SG
2844.40.0020	Other radioactive elements, isotopes, and compounds (includes promethium, gadolinium 157, and so forth)	Free	Free	
3606.90.3000	Ferrocium and other pyrophoric alloys	5.9% ad valorem	56.7% ad valorem	Free A+, CA, CL, D, E, IL, J, JO, MX, 4.4% (SG)
7202.99.5040	Other ferrosilicon alloys, containing by weight not more than 55% silicon, other (e.g., rare earth silicide)	Free	4.4¢/kg on silicon content	

* Products eligible for special tariff treatment:

A = Generalized System of Preferences (GSP) (duty-free treatment).

A+ = Only imports from least-developed beneficiary developing countries eligible for GSP under that subheading (duty-free treatment).

CA = North American Free Trade Agreement (NAFTA) for Canada (duty-free treatment).

CL = Chile Special Rate.

D = Africa Growth and Opportunity Act (duty-free treatment).

E = Caribbean Basin Initiative (CBI).

IL = Israel Special Rate (duty-free treatment).

J = Andean Trade Preference Act (ATPA).

JO = Jordan Special Rate.

K = Agreement on Trade in Pharmaceutical Products (duty-free treatment).

MX = NAFTA for Mexico (duty-free treatment).

SG = Singapore Special Rate.

Although REE raw material production is dominated by one country, worldwide REE commodity markets are complex because of the variety of ores and commodities. Also, REE separation facilities are located in various countries that import all of their plant feed material, which means that high-purity REE products may be shipped back to the countries that originally produced the REE raw material. France and Japan, which have no internal REE raw material sources, are major producers of processed REE commodities, exporting approximately \$20 million and \$15 million worth, respectively, of REE compounds and metals to the United States in 2003. Separated REE production in France is by a single company, Rhodia Electronics & Catalysis. Originally, it utilized monazite and xenotime from Australia and the United States; however, restrictions on the disposal of thorium waste forced Rhodia to shift to intermediate REE thorium-free compounds, including rare earth chlorides and nitrates. Sixteen European countries exported REE commodities to the United States in 2003: Austria, Belgium, Estonia, France, Germany, Hungary, Ireland, Italy, Liechtenstein, the Netherlands, Norway, Russia, Spain, Sweden, Switzerland, and the United Kingdom. At least 20 companies in Japan produce REE commodities that are used by that country's steel, auto, and electronics industries. Japanese REE producers have used increasing amounts of Chinese raw and purified REE materials for their industry.

GOVERNMENTAL CONSIDERATIONS

Tariff Rates, Depletion Provisions, and Government Policies

The classification of China as a most favored nation in 1978 by the United States had a strong impact on REE markets, and the U.S.

government has shown little interest in protecting domestic producers. U.S. tariff rates are shown in Table 9.

While keeping the value of its currency low, the Chinese government has aggressively promoted its REE industry. Peking University is reported to have a research staff of 1,400 scientists working on all facets of REE production and marketing (D. Witham, personal communication). Development of Chinese REE deposits does not seem to have been impeded by normal market considerations, leading to significant overproduction of REEs in recent years. Many of China's REE mines, processing facilities, and manufacturing plants are said to be underfunded (O'Driscoll 2003). In 2003, the Chinese government announced that it would assert control over its REE industry, setting up two oversight groups: one centered on the Bayan Obo-Baotou operations in the north and one that will be developed mainly around the lateritic (ionic clay) REE deposits in southern China.

Environmental Concerns

In the United States, REE mines and processing plants are required to meet the same environmental quality guidelines as other mining and chemical facilities. The U.S. Environmental Protection Agency (EPA) is responsible for setting air-, water-, and soil-quality standards for such operations nationwide, but standards for some individual states are more stringent. Reclamation requirements for mining are under state authority and differ from state to state; however, reclamation on federally owned land is overseen by agencies such as the U.S. Forest Service and U.S. Bureau of Land Management.

REE ores and commodities, as well as by-products and waste materials from REE processing, are naturally radioactive, mostly because of contained thorium. The thorium content of monazite typically ranges from 4% to 10% ThO_2 , where as thorium comprises less than 1,000 ppm in bastnasite from Mountain Pass (Mariano 1989a) and may be even lower in Chinese REE concentrate. Handling, shipping, storage, and disposal of such materials are controlled by federal and state agencies. Less than 10 t of thorium commodities, all from imported or stockpiled material, are consumed in the United States annually (Hedrick 2004b). Therefore, thorium produced during REE processing presents an expensive disposal problem for the industry.

The Rhodia plant in Freeport, Texas, extracted REEs from largely imported monazite until 1992, when the feedstock was switched to Chinese REE concentrates. Production from this operation has declined substantially in recent years. The company's La Rochelle, France, plant is now the world's only significant REE separation plant outside of China, and it imports most of its REEs as carbonates, chlorides, and nitrates from China (Chegwidden and Kingsnorth 2002).

Although the bastnasite produced by Molycorp, Inc., at Mountain Pass has relatively low thorium, chemical processing was suspended by the California EPA in 1998, mainly because of the radioactive element content of waste involved in a spill incident. Between 1998 and the present, Molycorp has sold REE commodities from stockpile and has purchased, tested, and resold imported REE commodities. The company plans to resume production at Mountain Pass and its environmental impact statement is currently under review.

Environmental concerns centered on the disposal of radioactive waste have precluded the development of REE extraction plants in Australia, where environmental policies are mainly under state control. A processing facility in Western Australia designed to produce REEs from 15,000 t of monazite annually, originally slated to begin production in 1989, was not constructed because of lack of approval from the Environmental Protection Authority of Western Australia. Groups concerned about radioactive contamination of the environment have become active worldwide, as shown by protests of plans to begin processing REEs in Malaysia in the late 1980s. Malaysian production of xenotime ore ceased in 1994 because of environmental regulatory compliance problems, along with the collapse of market prices for xenotime.

On the other hand, consumption of REEs in automotive and industrial emission catalysts is directly dependent on environmental regulations for air pollution control. Use and composition of REE-containing refinery FCCs are functions of both the feedstock and the fuel quality required, both of which also relate back to air pollution regulations.

FUTURE TRENDS

The future use of REEs is expected to increase, especially in automotive pollution catalysts, FCCs, and permanent magnets. Rare earth applications are expected to need greater amounts of higher-purity mixed and separated products, requiring specificity in their unique properties. Strong demand for cerium, lanthanum, and neodymium is expected to continue throughout the decade as automotive and electronic usage expands with population growth. Future growth also is forecast for REEs used in lasers, fiber optics, and medical applications that include MRI contrast agents, PET scintillation detectors, medical isotopes, and dental and surgical lasers. On the other hand, demand is expected to decline over the next decade for REE phosphors used in CRTs, as flat-panel display use increases. A slight decline also is forecast for rechargeable

nickel-hydride batteries, as lithium ion batteries gain wider use in portable electronics. Long-term growth is forecast for REEs utilized in magnetic refrigeration alloys and other technologies that exhibit energy efficiency and cost benefits.

World reserves are sufficient to meet forecast world demand well into the 21st century. Several world-class REE deposits in Australia and China (Mount Weld and Maoniuping, respectively) have yet to be fully developed and contain substantial reserves. Production may resume at idle deposits that produced in the past, such as Mountain Pass, United States, and Steenkampskraal, South Africa. Other substantial reserves are contained in heavy-mineral sands deposits worldwide. As demand continues to increase, future development of new REE deposits is likely.

U.S. companies have shifted away from using radioactive REE ores, which has negatively affected monazite-containing mineral-sands operations worldwide. The cost to dispose of radioactive waste products in the United States is expected to continue to increase, severely limiting domestic use of low-cost monazite and other thorium-bearing REE ores. Worldwide demand for monazite is expected to increase in the long term, however, because of its abundant supply and its recovery as a low-cost by-product.

World REE markets are expected to continue to be very competitive in response to China's large resources, competitive prices, low-cost wages, inexpensive utilities, and minimal environmental and permitting requirements. China is expected to remain the world's principal rare earth supplier. In addition, economic growth in several developing countries will provide new and potentially large markets in Southeast Asia and Eastern Europe.

The long-term outlook is for an increasingly competitive and diverse group of REE suppliers. As research and technology continue to advance the knowledge of REEs and their interactions with other elements, the economic base of the REE industry is expected to continue to grow. New REE applications are expected to continue to be discovered and developed.

Salt

Susan R. Feldman

Sodium is an unstable, silver-colored, metallic element that reacts violently in the presence of water, and chlorine is a dangerous and potentially lethal, greenish-colored gaseous element. Yet combined, these two elements form sodium chloride, commonly known as salt, which is a white-colored compound essential to life itself. Salt is perhaps the only mineral in the world that is used by virtually every human being. World history is peppered with examples of salt's profound influence. Sources of salt have even determined the location of cities, such as Salzburg, Austria; Salzgitter, Germany; and Saltville, Virginia. Populations have migrated in search of salt, and wars have been fought to obtain or to protect it.

Although there is no record of when prehistoric civilization first discovered salt, cultures appreciated its unique and distinctive taste. They also noticed animals attracted to salt springs and salt licks, satisfying their innate cravings. Hunters and gatherers knew that where there was salt, they would find animals. Because prehistoric people were not aware of their physiological need for salt, they automatically received their salt requirements from eating the meat of animals. A Mesopotamian tale tells of a wounded pig that ran into the ocean and drowned. After being recovered from the ocean, where it was saturated in the salt brine, the pork was found to taste better than unsalted meat. It was not until civilization graduated from a nomadic to an agricultural society and vegetables and cereals were introduced into the diet, that the need for additional supplements of salt was realized. The Sumerians ate salted meat and used salt to preserve food about 3500 BC. In approximately 1000 BC, the Trojans learned to use salt for preserving fish. The maritime civilizations, such as the Phoenicians, engaged in an extensive salt trade throughout the Mediterranean.

Many superstitions, customs, and traditions surround the religious, social, economic, and political aspects of civilization. Although some commodities have provided the basis of some ageless metaphors and clichés (i.e., heart of gold, strong as steel, eyes of coal), none are more commonly used as those pertaining to salt. Being “the salt of the earth” referred to a person's worthiness, as referenced in Matthew 5:13 of the Bible. Someone “not worth his salt” reportedly was used in ancient Greece in bartering salt for slaves. When laborers were worth their salt, they were paid a “salary” (*sal* is Latin for salt), a term still in use today that dates back to Roman times when part of a soldier's pay was paid in salt rations. Fearing those around him, the Roman leader Pompey was known to add a grain of salt to his drinks as a supposed antidote to poison.

Hence, “taking it with a grain of salt” is to regard something with suspicion. Kurlansky (2002) mentions that Haitians broke spells and brought zombies back to life with salt.

The earliest known record of salt production was in China about 2000 BC when Emperor Yu decreed that salt had to be supplied to the court as a tribute. Because salt was a commodity that had universal demand, governments often intervened to control salt production and distribution to generate revenue for major national projects. State-run salt monopolies were common in history—for example, in Rome about 506 BC. Revenue was also derived from taxes levied on salt sales. The word *gabelle* refers to the direct salt tax used in France. This tax was so despised that it was a major cause of the French Revolution. Although the tax was repealed in 1790, it was reinstated in 1805 to raise revenue for Napoleon's wars. France continued to use the *gabelle* until 1945. Because of the unique properties of preservation for food stores, salt became one of the first international trade commodities.

Salt making was an important economic activity in many areas of the world. Archaeological evidence indicates that salt was quarried from hills near the Dead Sea before the Bronze Age. At Hallstatt in the eastern Alps of Austria, rock salt was mined as early as 1400 BC. Solar salt was being produced in the northern Yucatan peninsula by the Mayan civilization about 1000 BC to AD 300; however, even earlier Mexican saltworks were found in Oaxaca. By the 1500s, salt was in such demand by civilizations that during the war beginning in 1568 between Spain and the Dutch, the Dutch were cut off from their supply of Spanish salt. They were able to confiscate Spanish salt from the beach at Araya in Venezuela and from sea salt ponds in Bonaire in the Dutch Antilles. The Spanish also lost salt to the British on Tortuga, another Caribbean island close to Venezuela. In 1541, when Hernando DeSoto, the explorer, was traveling up the Mississippi River, he remarked in his log that salt was collected along the river, marking the rudimentary solar salt gathering works by the native Indians of that region.

Other than the prehistoric use of salt in the southwestern part of the United States by Native Americans, the first production of salt by the American colonists began in June 1614 on Smith's Island, Virginia, 7 years after the founding of the Jamestown colony. The short-lived activity was in response to the high price of salt being charged by ships' captains who brought salt over as ballast from England.

History in the Americas is filled with salt wars. This trend continued until after the Civil War. The early Aztecs held power

over their enemies by denying them access to salt. Although Nathaniel Loomis, in 1790, is credited with starting the first commercial inland salt production in the United States at New York's Onondaga Lake, salt had been made by individuals for private use many years earlier. Indians had long known of the salt springs in the Kanawha Valley of Virginia (now West Virginia). In 1755, Mary Ingles, a white settler, was kidnapped by Indians and was forced to make salt from the saline springs. After her escape, she told other settlers how to make salt. At Saltville, Virginia, Arthur Campbell began making salt in 1782 by boiling brine obtained from salt springs. In 1799, William King sank a shaft about 3.0 m (9.8 ft) in diameter down about 61.0 m (200.1 ft) to the underlying Saltville salt deposits. The shaft flooded before he could extract any rock salt; however, King has the distinction of digging the shaft of the first salt mine in the United States. Figures 1 and 2 show the King site as it appears today in Saltville, Virginia. Production of brine from the shaft continued until 1892. Settlers moved into the Kanawha Valley in 1785, but it wasn't until 1806 that Elisha Brooks established the first commercial salt works in Kanawha.

GEOLOGY

In 1849, J. Usiglio, an Italian scientist, illustrated the sequence for precipitation of chemical compounds from sea water using water collected from the Mediterranean Sea. His order of precipitation was iron hydroxide, calcium carbonate, calcium sulfate, sodium chloride, and the soluble salts of potassium and magnesium in the mother liquors. Although the deposit at Strassfurt, Germany, is a classic example of this sequence, this sequence was not correct.

Mineralogy

Pure sodium chloride contains by weight 39.34% sodium and 60.66% chlorine. The mineralogical name for salt is halite, from the Greek word *hals*, meaning salt. Because of its simple crystal structure, it was the first structure to be analyzed by x-rays. Salt has the following properties:

Formula: NaCl

Crystallography: isometric, hexoctahedral, 4/m 32/m

Cell contents: Na₄Cl₄

Habit: usually cubic, rarely octahedral; massive, granular to compact

Physical properties:

Refractive index: 1.554

Twinning: observed on {111}

Cleavage: {001} perfect

Fracture: conchoidal, brittle

Hardness: Mohs hardness of 2

Specific gravity: 2.168

Melting point: 804°C (1,479°F)

Boiling point: 1,413°C (2,575°F)

Luster: vitreous, normally colorless to white, but occasionally red, yellow, blue, and purple

Solubility: 0°C: 35.7 parts per 100 parts of water
100°C: 39.8 parts per 100 parts of water

Classification of Deposits

Salt deposits are found in solution or in a solid state. It is the method of recovery from these two forms that categorizes salt as rock salt, solar salt, salt brine, or vacuum pan salt.

Solution

Solutions of salt are found in the oceans, lakes, natural brines, and groundwater.

Oceans. The oceans provide us with the largest resource of salt in the world. The world's oceans contain about 530 million km³ of water. About 42% of salt is dissolved in the oceans. One cubic kilometer of seawater contains 93 Mt of dissolved matter, of which 78 Mt is salt. To visualize what this quantity of salt looks like, it would take about 18 Vertical Assembly Buildings (the world's largest building in terms of volume) like the one at the Kennedy Space Center at Cape Canaveral, Florida, to hold all the salt contained in a single cubic kilometer of seawater.

The salt content of the oceans varies from 1% to 5%, depending on the location, depth, and external influences, but it averages about 3.5%. In coastal areas, where evaporation rates exceed precipitation rates, solar evaporation of sea water may be the more advantageous method to produce salt. In certain countries that have limited technology and markets, the operations may be crude and

relatively unchanged from methods their ancestors used. Some facilities in arid regions take advantage of natural, shallow depressions along the coastlines. The seawater is introduced during high tides or storms and evaporated during dry periods, leaving a dry crust of salt on the surface. Most of these operations are small and the salt is marketed for local consumption. In other nations, modern operations that use more advanced scientific techniques to improve product quality and quantity while maintaining low production costs have become major competitors in world markets.

Lakes. Lakes are the result of natural accumulations of water in topographical depressions, or behind natural obstructions. Usually water carries dissolved material whose composition depends on the type and solubility of the rocks and material exposed to dissolution by the ground and surface waters. Clarke (1924) classified mineralized lakes as follows

- Sodium chloride lakes
- Natural bittern lakes—magnesium salts dominate
- Sulfate water lakes
- Sulfate-chloride lakes
- Alkaline lakes; carbonate lakes, carbonate-chloride lakes, chloride-sulfate-carbonate lakes

Sodium and calcium cations that dominate most mineralized lake deposits give rise to deposits rich in sodium sulfate (both mirabilite and thenardite), burkeite, gaylussite, trona, and halite. Landes (1960) reported that the sodium chloride lakes are “either separated bodies of ocean water or they owe their composition to the presence of salt within the rocks that floor the watershed.” Land-locked bodies of saline water provide a natural source of salt to develop, such as the Great Salt Lake in Utah, where several solar salt evaporation facilities have been constructed. Alkaline lakes, such as Searles Lake and Owens Lake, both in California, are more noted for their sodium carbonate content than their sodium chloride potential.

Groundwater. Groundwaters are classified as either connate or meteoric water. Connate waters are those that are trapped in the country rock at the time of formation and reflect the composition of the water at the time. Most sedimentary rocks were deposited at the bottom of the sea, so a substantial quantity of connate water could have been entrapped during the process. However, sedimentary rocks are also formed in freshwater lakes and interior salt lakes.

Meteoric, or rainwater, is fresh as it is precipitated; however, it absorbs soluble material as it descends through the air, and into the soil, rocks, and so forth. Depending on the environment, the composition and the salinity of groundwater vary. The salinity of the groundwater can increase on contact with sodium chloride-rich strata. Clarke (1924) classified groundwaters into the following groups: chloride, sulfate, carbonate, mixed (chloride-sulfate, chloride-carbonate, sulfate-carbonate, chloride-sulfate-carbonate), siliceous, borate, nitrate, phosphate, and acid.

Groundwaters range in chemical content from practically nil to as much as 254,000 ppm. Many groundwaters that were saturated with salt provided the source of surface salt springs that were used by animals and prehistoric man. The salt-bearing groundwaters in New York, Virginia, and West Virginia were commercialized to take advantage of this resource. Some brines are not processed for the salt but for their bromine or magnesium contents.

Solid Salt

Crystalline salt is found in playa lake deposits, bedded salt deposits, and salt domes. Halite may be the dominant mineral; however, it also may be commingled with other sedimentary minerals.

Playa Salts. A playa is a naturally occurring sandy, salty, mud-covered floor of a desert basin, according to Grabau (1913). During

an influx of rain, the playa may be covered with rainwater, which dissolves part of the soluble playa surface. After the water evaporates, a soluble evaporite remains that may be concentrated in one part of the playa. With subsequent periods of additional precipitation and evaporation, salts dissolved from the playa surface will deposit out as crystals of various substances, the majority of which is sodium chloride. The crystal's surface promotes the continued growth of the size of the crystalline deposit. Searles Lake in California is considered one example of a crystal body in a playa lake.

Playa lake deposits generally are common in arid regions. Saline playas are formed from the evaporation of a mineralized lake that was created by the leaching of the rocks in the area surrounding the enclosed basin. Sodium chloride-bearing solutions contribute to the salt content of the playa. The presence of certain other minerals may indicate that other geologic processes occurred in the area. For example, the presence of borates would indicate recent volcanism in the area.

Salt is not the only mineral found in playa deposits. The mineralogical composition of a playa may vary considerably. Several playa lakes in California illustrate this clearly. Cadiz Lake is predominantly composed of calcium chloride, while Bristol Lake is predominantly salt and Owens Lake is chiefly sodium carbonate. Searles Lake contains a mixture of many compounds, primarily salt, sodium carbonate, sodium sulfate, potash, and borates.

Bedded Salt Deposits. Salt is also found as sedimentary, bedded deposits of varying thicknesses. It is usually associated with other sedimentary rocks, such as shales, limestone, dolomites, gypsum, anhydrite, and so forth. Salt deposits are found in every geologic period from the Cambrian to the Tertiary, and evidence indicates that some deposits are Precambrian. Table 1 lists examples of salt deposits in the different geologic periods.

Although bedded salt deposits are found in many countries throughout the world, geologists have been intrigued with the origin of the very thick deposits, such as Paradox Basin, some of which exceed several hundred meters in thickness and cover many hundreds of square kilometers. The concept of the time span and the amount of evaporation required to produce that magnitude of salt overpowers the imagination.

Various theories have been developed to explain the formation of bedded salt deposits. None of the ideas adequately account for the extremely thick beds, or for the concept of how salt may be the dominant mineral in one basin with gypsum-anhydrite in another. The generally accepted theory of formation involves the precipitation of salt from an evaporating body of salt water. Landes (1960) outlined the classification of the various theories as follows

- I. Terrestrial type: Evaporating interior sea becomes saline as a result of
 - A. Primary sodium chloride produced as a weathering product.
 - B. Flushing of connate water from sedimentary rocks cropping out above water level in drainage basin.
 - C. Leaching of salt from sedimentary rocks cropping out in the drainage basin.
- II. Marine type: Concentration of ocean water in cutoff sea:
 - A. Without further enrichment
 - B. With enrichment by
 1. Wind-blown salt
 2. Ocean water
 - a. Marginal salt pans
 - b. Marine salinas
 - c. Barred lagoons
 - d. Silled downwarping basins

Table 1. Ages of salt deposits

		Location
Cenozoic Era		
Recent		Mexico, United States* (solar salt operations and playa lakes)
Pleistocene		Israel, Mexico, United States (CA, NV), Russia
Pliocene		Italy, Jordan, United States (NV, UT)
Miocene		Algeria, Cyprus, Czech Republic, Dominican Republic, Egypt, Iran, Iraq, Morocco, Poland, Spain, Sudan, Syria, Trucial States, Turkey, Russia
Oligocene		France, Germany, Iran, Iraq, Spain, Turkey
Eocene		Belize, Iran, Morocco, Pakistan,† United States (Green River Basin, WY)
Mesozoic Era		
Cretaceous		Angola, Bolivia, Brazil, Colombia, Congo, Gabon, Libya, Mexico, Morocco, Nigeria, Peru, Senegal, United States (FL), Russia, Democratic Republic of Congo
Jurassic		Aden, Chile, Cuba, Germany, Kuwait, Tanzania, United States (ID, Gulf Coast area)
Triassic		Algeria, Bolivia, Bulgaria,† Ethiopia, France, Germany, Greece,† Libya, Mexico (Isthmus of Tehuantepec), Morocco, the Netherlands, Peru, Portugal, Spain, Switzerland, Tunisia, United Kingdom
Paleozoic Era		
Permian		Australia,† Brazil, Denmark, Germany, Greece,† the Netherlands, Mexico, Peru, Poland, United Kingdom, United States (Permian Basin, Supai Basin, Williston Basin), Russia
Pennsylvanian		Brazil, United States (CO, UT, Paradox Basin)
Mississippian		Canada (New Brunswick, Nova Scotia), United States (VA, Williston Basin)
Devonian		Australia, Canada, United States (Williston Basin, WY), Russia
Silurian		Canada, United States (Salina Basin)
Ordovician		Bolivia,† United States (Williston Basin, WY)
Cambrian		Australia, Canada (Northwest Territories), Iran, Pakistan,† Russia
Precambrian Era		
		Australia, Iran, Pakistan†

Adapted from Lefond 1969.

* See Figure 3 for more information on U.S. deposits.

† Unconfirmed.

Landes (1960) also suggests the following stages for the formation of a major bedded salt deposit:

1. Peneplanation of the continental platform so that it is a nearly flat land of very little elevation above the sea.
2. Submergence of wide areas beneath the sea. Shallow ocean waters spread over a considerable part of the continent.
3. Beginning or renewed downwarping of a basin marginal to this epicontinental sea.
4. Sedimentation of both basin and epicontinental sea. Mainly clastic and organic (reef) deposits.
5. Lowering of sea to approximately sill level. Period of evaporite deposition. Enrichment by seawater flowing across sill. Because of the shallowness of the water, and the distance from the open ocean in such areas as the Michigan Basin, the brine crossing the sill may have been abnormally strong. Some enrichment could also take place by wind-blown salt, for the flat topography and scantiness of land vegetation no doubt resulted in incessant winds of considerable magnitude.

As more salt and/or sediments are deposited onto the layer of salt crystals on the sea floor, the water is squeezed out and the salt crystals become compacted or recrystallized into massive salt beds. Other theories of salt formation suggest that salt may have been deposited from deep density-layered brine contained in basins that did not dry up. This theory raises more questions than it resolves.

Salt Domes. One of salt's properties is that it will flow plastically when compressional forces are exerted on competent strata that contain salt beds. The forces may be due to the static weight of

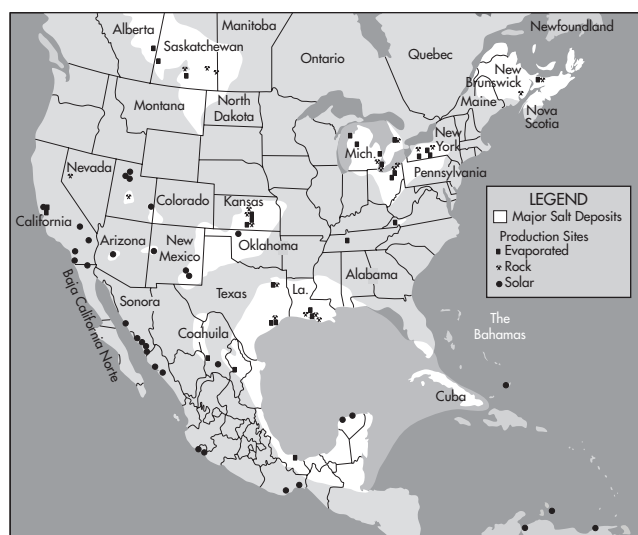

the overlying sediments, or other tectonic factors. If the pressure increases, the salt will flow into zones of decreased pressure, usually vertically upward through the overlying sediments. The salt will resemble "domes" or "diapiric folds." Salt domes are found in the Gulf Coast of the United States and in the Paradox Basin of Colorado-Utah. They are also found in Algeria, Germany, Iran, Mexico, Romania, Tunisia, and elsewhere. Some times the salt dome reaches the surface and appears as a circular expression, such as the Avery Island, Louisiana, salt dome. A salt dome can also flow like a glacier onto the surface, such as the Kuh-i Namak salt plug in the Persian Gulf area.

Distribution of Major Deposits

Solid deposits of salt or salt-bearing solutions are found in virtually every country in the world. Although the world contains abundant reserves of salt, the location and size of the deposits in relation to the location and size of the salt markets are important factors to consider when developing a commercial salt operation. For example, transportation is a variable in the total cost to the purchaser. To remain competitive, these types of added expenses must be evaluated to determine whether a business in a particular location makes sense economically.

The United States

The United States is the world's largest salt producer. Its domestic salt resources are located primarily in four depositional basins covering an area totaling about 1.3 million km² (0.5 million mi²) in 18 states. Figure 3 shows the distribution of domestic (North

Adapted from Salt Institute 2004.

Figure 3. Major salt deposits and dry salt production sites in North America

American) salt resources. Although large regions of the country are underlain with bedded, dome, or brine salt deposits, the northwest and most of the eastern States are devoid of salt. For consumers located in these regions, salt must be imported. The total identified resource of salt in the United States is estimated at 49.8 trillion t. At the present rate of mining, only 45 Mt are being depleted annually from this resource.

The four depositional basins are (1) the Gulf Coast of Permian-Jurassic age, which covers part of Alabama, Arkansas, Florida, Mississippi, eastern Texas, and all of Louisiana; (2) the Permian of Permian age, which includes part of Colorado, Kansas, New Mexico, Oklahoma, and western Texas; (3) the Salina of Silurian age, which covers part of Michigan, New York, Ohio, Pennsylvania, and West Virginia; and (4) the Williston of Ordovician-Permian age, which includes portions of North and South Dakota, Montana, and Wyoming. The Salina and Williston basins extend into Canada while the Gulf Coast and Permian basins reach into Mexico.

There are also a few other minor basins that contain salt. They are (1) the Supai of Permian age, in part of eastern Arizona and western New Mexico; (2) the Paradox of Pennsylvanian age, in southeast Utah and southwest Colorado; (3) the Sevier, in central Utah; and (4) the Green River of Eocene age, in southwest Wyoming. There is also some bedded salt in the overthrust area of Utah/Wyoming.

World

Salt is produced in Canada in the provinces of Alberta, New Brunswick, Nova Scotia, Ontario, Quebec, and Saskatchewan. Although Canada has large reserves of salt, about 62% of Canadian salt production is in Ontario, where transport economics are the dominant market force.

Rock salt deposits in Mexico occur near Monterrey, Coatzacoalcos, and Punta Gorda. Salt domes and salt anticlines are associated with the deposit at Coatzacoalcos. At Monterrey, the salt is solution mined and used as feedstock for the one local synthetic soda-ash plant. Although there were extensive solar works in the northern Yucatan peninsula that had been used by the early Mayan

civilization, the major solar salt production in Mexico today is at Guerrero Negro along the Pacific coast of Baja California.

Brazil has large salt reserves in the Amazon basin, Sergipe, and in offshore salt domes. Salt is also found in Argentina, Chile, and Colombia. Except for the underground salt mine at Zipaquirá, Colombia, the majority of salt produced in South America is from playa lake deposits or solar salt pans.

The salt industry of Europe can be traced back to early Roman times. The Romans introduced open-pan evaporation of seawater to England. Salt has been produced in Austria since the eighth century, and the rock salt mine at Wieliczka, Poland, has been in continuous operation since the thirteenth century. England, France, Germany, Italy, the Netherlands, Poland, and Romania, and Russia are the major salt-producing countries of Europe. Approximately one-fourth of the salt produced is rock salt, and most of the remainder is salt brine for use by the European chemical industry.

One of the major salt deposits in Europe is the Zechstein (Permian) salt formation that extends from eastern England to western Poland. In Germany, the Keuper (Triassic) salt beds are well developed. Salt beds of the Miocene, Oligocene, and Jurassic periods are found in several European countries. Solar salt is produced along the coasts of France, Greece, Italy, Portugal, and Spain.

Although rock salt deposits are found in Africa, most salt is produced by solar evaporation from seawater and saline lakes. The countries that are known to produce salt include Algeria, Benin, Burkina Faso, Djibouti, Egypt, Ghana, Kenya, Libya, Madagascar, Mali, Mauritania, Mauritius, Morocco, Mozambique, Namibia, Niger, Senegal, Sierra Leone, Somalia, the Republic of South Africa, Sudan, Tanzania, Tunisia, and Uganda.

China is the largest salt-producing nation in Asia and the second largest in the world. Coastal solar salt works and inland drilling for salt brines have been conducted since about 2000 BC. Though a major salt user, Japan has no indigenous rock salt or salt spring deposits; therefore, it must depend on imports to satisfy most of its salt requirements. Japan does, however, produce food-grade salt by processing seawater using ion-exchange electrodialysis technology, which is very energy intensive. The improper climate and lack of available coastal land make solar salt production impractical. Rock salt deposits in Asia are found in China, India, Pakistan, and Thailand. Within the last decade, countries such as India, Pakistan, Thailand, Vietnam, and many African coastal nations have begun to explore the commercial aspects of solar salt production, and many have developed production sites.

TECHNOLOGY

Exploration and Development

Many salt deposits were discovered while exploring for oil, gas, and potash. For example, salt was found in Morocco's Mohammédia region by a United Nations exploration team searching for commercial-grade potash in the Khemisset-Berrechid basins. Accidental discoveries of salt occurred in Brazil, France, Morocco, Portugal, and Thailand.

Although many reconnaissance projects have located salt resources, it is the task of the exploration geologist to delineate the ore zone and attempt to quantify the salt reserves. The exploration method is governed to a large extent by the proposed method for recovering the salt—that is, by either conventional underground room-and-pillar mining or by solution mining, including the projected use of the resultant cavity.

If the salt body is to be dry mined, the exploration project must be more extensive and greater care taken in delineating the

results than if the deposit were to be mined using solution-mining techniques. The extra care is necessary because of the greater capital investment incurred with underground dry mining than is incurred in developing a brine field.

Evaluation of Geologic Factors

When evaluating a salt deposit for dry mining, the geologic conditions surrounding the deposit are almost as important as the deposit itself. These conditions include

1. *Groundwater.* The quantity of groundwater and its hydrostatic head will have a direct influence on the method and cost of shaft sinking. If the groundwater is a potable water supply for a community, the protection of the aquifer requires careful hydrological investigation. Shaft sinking difficulties will increase if an aquifer contains brine or significant amounts of hydrogen sulfide, ammonia, or hydrocarbon gases, or if the hydrostatic pressure is very high.
2. *Overburden characteristics.* Considering the overburden as the alluvium plus the rock sequences above the salt deposit, it is essential that the physical characteristics of these horizons be known as fully as possible. It is particularly important that this information is gathered from the area in which the shaft or shafts are to be sunk. The data should include the thickness and hardness of the beds, drillability, fracture pattern, friability, and tendency to oxidize. Contractors that sink the shafts frequently make physical examinations of the drill cores themselves.
3. *Physical characteristics of rocks associated with the salt.* The structural integrity of the sedimentary rocks underlying and overlying the salt bed is particularly important. The roof spans, pillar size, percentage of extraction, mine layout, and the roof-bolting program are some of the mine features that will be dictated by the character of the rocks surrounding the deposit.
4. *Faults.* Fault systems, common to many salt formations, can create numerous serious problems and should be defined as carefully as possible during the exploration project (Jacoby 1969). Salt domes in the United States gulf coastal area have many faults associated with the spines that characterize their upper limits. These vertical or near-vertical fractures often contain brine, oil, and/or gases. Failure to develop mining patterns to a void creating differential stresses across these features to seal off the liquid intrusions often results in great expenditures of time, energy, and money.
5. *Facies changes.* Major and minor facies changes may occur in salt beds over relatively short distances. This has been documented in the Michigan Salina salts; the Realmonte, Sicily salts; and the potash salts of the Khemmiset Basin of Morocco. In Michigan, the A-1 salt changes from a pure anhydrite on the basin's edge near Detroit to an almost pure salt in East China Township, Michigan, and finally to a heavily contaminated potash salt at Midland. In the Khemmiset Basin, salts grade from a lean potash ore at Berrechid to a 98.3% sodium chloride in Mohammadia. Although the salt at Realmonte, Sicily, is metamorphosed, it shows a similar gradational change from lean potash mineralization to a pure halite. Most salt consumers prefer a product of uniform chemical composition; therefore, the exploration program must define the limits of the various salt grades laterally and vertically within the bed and the reserves of a uniform or standard product.
6. *Attitudes and position.* The attitude and position of bedded salt and the flowage lines in salt domes influence the mining

system, the percentage of extraction, the depth of the mining level, the selection of a shaft versus an inclined entry, and the rock mechanics of superimposing pillars where multiple level systems are contemplated. Whenever the internal features of the deposit or the continuity of the salt quality is questionable, a mill sample should be obtained by a bored shaft or inclined entry. Structures within a salt bed, such as folding (e.g., Cane Creek potash mine in southern Utah), can also add problems to underground mining. In the case of Cane Creek, this structural change caused the owners to switch to solution mining from underground mining. When solution mining is considered, exploration is conducted concurrently with the expansion or replacement of the current brining facilities. Evaluating the regional geology leads to the selection of the brine field site. Based on previously published information, a decision may be made on whether or not geophysical information would be beneficial in guiding subsequent drilling. Where domes are involved, or where the beds are known to have been altered by diapirism or faulting, geophysical studies may have distinct value (Mattox 1968).

7. *Chemical composition.* The deposit generally should have a minimum sodium chloride content of 95% to be commercially acceptable. The northeastern section of the United States has an average sodium chloride content of 97%. Salt obtained from southern salt domes or from solar evaporation has a higher sodium chloride content of about 99%. Depending on the salt end use, various trace elements such as boron, chromium, copper, iron, and vanadium, as well as ammonia, and water insolubles, such as gypsum, must be considered.

Drilling and Coring

If seismic or other geophysical data show a uniform top elevation of the salt, the drilling fluid can be changed from water to saturated brine just above the top of the salt formation. Where zones of lost circulation have been encountered "up the hole," a casing point is usually selected above the top of the salt and a string of protective casing installed. Depending on the well design and the economics, the casing is either set temporarily on a packer or permanently cemented in the hole. When drill holes expose shales that swell, spall, or slough in the presence of freshwater, early conversion to a saturated salt-brine drilling fluid often is justified.

A clean and fully saturated or supersaturated brine drilling fluid is very important so that the salt is not etched or leached. The solubility of salt at different temperatures is also very important.

Once the drill rig cuts and recovers the cores, the cores are cut into 0.33 m (1 ft) lengths and halved. One section is halved again to form a quarter, which is crushed and ground for chemical tests. Physical testing is usually done on a second quarter of the core.

Once the core hole is completed, it should be logged with gamma-neutron, sonic, or 3-dimensional equipment. The logs are then correlated with the physical core sections and the geograph that records the rate of drill penetration. Because faults, especially low-angle thrust faults, are difficult to recognize in cores of salt beds, the correlation with logs will often show repeat sequences of rock strata. Subsequently, a core reexamination may indicate a fine-grained granular halite section of core that was previously unrecorded. Sonic logging differentiates anhydritic dolomite from dolomitic anhydrite, while gamma-neutron will clearly depict salt from anhydrite (Leroy 1951).

Evaluation of Deposits and Plant Siting

Jacoby (1972) outlined a good procedure for evaluating a salt deposit with respect to its development using solution mining:

- I. Preliminary considerations
 - A. Plant requirements
 1. Quantity of brine
 2. Quality of brine
 3. Degree of saturation required
 - B. Subsurface factors
 1. Geology
 2. Rock mechanics
 3. Hydrology
 4. Previous extractive operations and environment
 - C. Surface factors
 1. Environment
 2. Topography
 3. Property boundaries
 4. Plant-brine field relationships
 - D. Feasibility study
 1. Preliminary brine-field layout
 2. Capital investment
 3. Cost of capital
 4. Operating cost
 5. Brine treatment cost
 6. Taxes and tax incentives
 7. Return on investment
- II. Preliminary engineering
 - A. Property
 1. Acquisition
 - a. Option of surface and mineral rights
 - b. Rights of well sites
 - c. Ingress and egress rights
 - d. Right-of-way for roads, pipelines, and power lines
 - e. Storage rights
 - f. Conditions of abandonment
 - B. Water supply
 1. Environmental considerations
 - a. Groundwater table
 - b. Salt water encroachment
 - c. Effect on local agriculture, industry, and domestic use
 2. Supply characteristics
 - a. Volume (continuity and cyclic variations)
 - b. Quality
 - C. Salt supply
 1. Exploration
 - a. Geophysical surveys
 - (1) Seismic
 - (2) Gravity
 - b. Drill holes
 - (1) Cores
 - (2) Geophysical logs
 - (3) Hydrological tests
 2. Design data development
 - a. Analyses of well logs and cores
 - b. Physical testing of cores
 - c. Water supply evaluation
 - d. Equilibrium studies
- III. Design and cost analysis
 - A. Brine-field layout and cost
 1. Salt wells design and cost
 2. Subsidence grid system design
 3. Roadways and well sites
 4. Pipelines and power lines
 5. Cathodic protection

6. Pump and pump facilities
7. Feedwater treatment facilities
8. Reservoirs and aeration
9. Security
- B. Supervision costs
- C. Operating costs
- D. Maintenance costs
- E. Taxes and insurance
- F. Depletion and depreciation
- G. Cost of capital
- H. Return on investment

Methods of Recovery

Data pertaining to commercially produced salt in the United States have been reported since 1797. A good reference for this is Kaufmann (1960). Table 2 lists domestic salt production, by type, from 1990 through 2002.

Underground Mining

Mining underground bedded salt or salt dome deposits includes constructing and developing underground rock salt mines, solution mining of the subsurface solid salt, or producing and developing natural saline brines.

Rock Salt Mining. All U.S. and Canadian rock salt mines use the room-and-pillar method of underground mining. The height of the pillars is limited to the thickness of the salt bed and the vertical section of salt that can be economically and safely extracted. Usually a certain amount of salt is left behind in the floor and the roof to avoid mining into the underlying and overlying non-salt beds that would contaminate the quality of the salt being mined. Bedded salt deposits generally are vertically restrictive but laterally unrestricted, while salt dome deposits are laterally restricted but vertically unrestricted. Room heights can range from about 3.0 m (9.8 ft) in a bed to more than 30.0 m (98.4 ft) in a dome. The height of pillars in salt domes, therefore, can be substantially higher than those in bedded

Table 2. Salt production in the United States, kt*

Year	Vacuum Pans and Open Pans	Solar†	Rock‡	Brine§	Total**
1990	3,660	2,990	12,800	17,400	36,800

Figure 4. A 1939 view of Cargill Salt's Avery Island rock salt mine

salt operations. The room widths are basically a function of the thickness of the overlying incompetent rocks and the physical characteristics and thickness of the salt that forms the roof. Figure 4 shows a view of Cargill Salt's Avery Island rock salt mine with its rooms that are 30.0 m (98.4 ft) high.

The pillar widths are controlled by the percentage of extraction permissible at the various depths and room widths. Most room-and-pillar operations recover about 45% to 65% of the resource, with the remainder left behind as pillar supports. Most mines in bedded deposits use roof bolts to support their haulage ways, shaft entries, and permanent work areas. Roof bolts are used in bedded salt mines to prevent roof collapses. They are effective safety devices when properly applied. The length, diameter, and spacing of the bolts vary with the circumstances. Most mines use bolts 1.1 m (3.6 ft) to 3.0 m (9.8 ft) long on 1.1 m (3.6 ft) spacing centers. Very little roof bolting is done in salt dome mines because of the problems encountered in bolting in salt. Bolt holes in salt have a smooth, slick surface that form poor seats for bolt anchors, and that deforms plastically over time because of the pressures.

The majority of domestic rock salt mining uses conventional mining equipment because of the physical properties of salt. Continuous mining equipment, which uses rotating drum heads fitted with tungsten-carbide cutting tips, has been tested in some mining operations, but it tended to pulverize a lot more of the salt into useless fine particles. Newer types of continuous mining equipment have improved to such a degree that they are finding wider acceptance in salt mining. In conventional mining, the working face is first horizontally undercut about 3.0 m (9.8 ft) into the face to produce a keel. This allows a smoother floor to work from later on. Next, a drill rig is used to drill a series of horizontal (or slightly angled) holes about 3.0 m (9.8 ft) deep into the salt. Explosives, usually ammonium nitrate and fuel oil (ANFO), are pneumatically blown into the drill holes and set off electrically later after the working shift is over. One Kansas mine has experimented successfully with making the first horizontal cut at the ceiling level, rather than along the floor. The result is a smooth ceiling.

After the salt is blasted free, front-end loaders pick up the loose rock salt and transport it to a breaker-feeder unit that crushes and conveys the salt on belt conveyors to other underground crushing and screening stations. The salt can be stockpiled underground or hoisted to the surface and stored in silos or bins for processing at

a later time. Some operations prefer to crush and screen the salt to different sizes at the surface.

In 2004, eight companies operated 14 rock salt mines in the United States. The plant locations span Kansas, Louisiana, Michigan, Nevada, New York, Ohio, and Texas. Rock salt mining accounted for 400 Mt, or 66% of total U.S. salt production in 2002.

Solution Mining. The practice of solution mining is more than 2,200 years old; however, the concept remains the same today although there have been a few improvements made since 1965. Solution mining involves injecting a solvent to dissolve and recover underground soluble minerals. Before 1955, all solution mining used either "annulus injection" that employed a pair of concentric pipes (one carried the solvent downward and the other contained the brine upward) or "tubing injection" that introduced the solvent at the bottom of the tube. Several holes are usually drilled and the solvent (usually water) is pumped into the holes under pressure, dissolving the salt and leaving the insolubles in the bottom of the resulting cavity. The saturated brine can be pumped to the surface for recovery and further processing. One advantage of this technique is that specific beds can be mined, thereby reducing any subsidence.

Hydraulic fracturing has been used in the oil and gas industry for many years and was adopted by the salt industry. This technology was preferred for the following reasons:

1. It altered the cavity configuration from the "morning glory" shape to hemispheres and ellipsoids, thus increasing the stability of openings and reducing the likelihood of subsidence.
2. It increased the percentage of extraction from less than 5% to something in excess of 40%.
3. It reduced brining costs in most operations by 50%.
4. It increased the productive capacity of wells from approximately 3 L/s (50 gpm) to about 31 L/s (500 gpm) or more.
5. It reduced well maintenance costs to less than 5% of their former amount.

Solution mining is used to obtain a sodium chloride feedstock for vacuum-pan salt production and for synthetic soda ash, chlorine, and caustic soda manufacture. Only the quantity of manufactured vacuum-pan salt is reported. The amount of underground salt that is dissolved and recovered is not reported. The quantity of brine used to make chloralkali chemicals is reported as either the amount of captive brine used or brine sold. The chemical industry is the largest consumer of salt brine in the world, using about 45% of total salt sales. Brine represented about 89% of the salt feedstock for the chemical industry. Although the same companies that use it produce most salt brine, many chloralkali manufacturers now purchase brine from independent brine supply competitors.

Most salt and chemical companies use contract drillers to drill brine wells. Almost all new wells are constructed with rotary drilling equipment. Steel-cased pipes are inserted in the drill holes and cemented on the outside back to the surface. Most companies use a series of well pairs to establish a brine field. One well pair consists of (1) an injection well, in which the water solvent is introduced, and (2) a production well, in which the salt-bearing solution is pumped to the surface for processing. Some chemical companies have turned over the routine responsibility of operating and maintaining the brine field and pipelines to brine supply companies. The chemical producers are charged by the meter for how much brine they receive.

The cavities created during solution mining are often used for underground storage of a variety of products. The empty caverns

provide an inert and sealed environment to store hydrocarbons, ethylene dichloride, and compressed air.

Solar and Mechanical Evaporation

Other than recovering salt from underground deposits, salt can be obtained from seawater along coastal margins, and from landlocked bodies of natural saline water and artificial brines. Salt production uses the wind and sun to evaporate water, leaving behind relatively pure crystals of salt. Solar salt production is restricted to regions of the world that have high evaporation rates and low precipitation. The practice of solar salt production from sea water can be traced back many hundreds of years and has not changed much throughout history. Laborers in some countries today, such as Colombia, India, Jordan, and Thailand, continue to produce solar salt in the same manner as their ancestors.

Seawater Evaporation. Seawater contains various dissolved salts that will separate depending on their relative solubilities. Calcium carbonate, which is the least soluble, will separate out first. Highly soluble magnesium salts tend to separate last. The mineral salt separation order from seawater, from first to last, is calcite, gypsum, halite, astrakanite, epsomite, kainite, hexahydrate, kieserite, carnallite, and bischofite.

In the United States, solar salt production from sea water is restricted to the San Francisco Bay area and southern California. Seawater from the Pacific Ocean is collected and allowed to evaporate in specially constructed concentration and evaporation ponds. The initial step concentrates the brine to raise the salinity and to allow various calcium, magnesium, and iron compounds to precipitate from solution. The brine circulates among a network of interconnecting gravity-fed ponds, with salinity increasing with each transfer. It takes approximately 2 to 5 years from the time seawater is initially introduced before the first salt is ready for harvest.

The brine is treated with lime to remove excess sulfate as calcium sulfate and then pumped to evaporation ponds and harvesting ponds to permit the salt to crystallize. After about 85% of the salt has crystallized, the remaining supernatant liquid, called "bittern," is drained. Some companies pump the bittern to adjacent ponds for subsequent extraction of magnesium, potassium, bromine, and sodium compounds. Depending on the location of the plant, frequency of harvest can vary. In most industrialized countries, solar salt is harvested by mechanical harvesting equipment. Less industrialized countries still use manual labor to obtain the salt.

Inland Solar Evaporation. Solar salt is produced from the Great Salt Lake in Utah, which is an example of a landlocked body of salt water. The principles of solar salt concentration and production are similar to those along coastal margins except that salinity of inland lakes usually is greater than that of seawater and a yearly crop of salt can be harvested. As water flows over or beneath the surface, it dissolves minerals from underlying soils and rocks. The salt lakes are topographically lower than most of the surrounding areas and, therefore, become excellent sumps for mineral accumulation. For example, the Great Salt Lake receives about 2 Mt of new minerals annually by this process. The salt percentage in the lake varies, depending on the influx of freshwater.

A second form of inland solar evaporation includes evaporating artificial brines that were discharged as waste products into containment ponds. One example is the solar salt operations in New Mexico that are associated with potash mining. Underground-commingled deposits of halite and sylvite are mined for the potash, and the salt is discharged during potash processing as a brine to tailing ponds and left to evaporate. Over the years, many feet of salt have accumulated and various companies have been attracted to recover and sell the salt. Although a network of concentration and evaporation ponds is

not required in this case, the harvesting equipment is similar. The arid location permits virtually year-round harvesting.

The total quantity of solar salt produced in 2002 in the United States was 3.4 Mt, or 8.4% of U.S. salt production. Nine salt companies operated 14 solar evaporation facilities in the United States. Solar salt from seawater was harvested in California. Solar salt from inland solar evaporation was produced in Arizona, California, New Mexico, Oklahoma, and Utah.

Vacuum Pan Salt

Vacuum pan salt is solution- or dry-mined and is produced using mechanical evaporation technology. Although any of the other three types of salt may be dissolved to make vacuum pan salt (i.e., rock salt, solar salt, and salt brine), virtually all domestic vacuum pan salt is obtained by solution mining underground salt formations.

Salt is obtained by dehydrating the incoming brine using heat alone or in combination with a vacuum. The vacuum pan process conserves energy by using multiple-effect evaporators connected to vacuum pumps. A saturated salt solution will boil at a higher temperature than freshwater; however, when a vacuum is applied, the brine boils at a lower temperature, enabling the generated superheated vapor to act as the heating medium for the next evaporator.

Another mechanical evaporation process used in the United States on a small scale is the open-pan process. Round and rectangular pans with steam-heated immersion coils are used to evaporate the water from the brine. Rotating rakes scrape the salt that has accumulated on the pan bottom into a sump, or up a ramp depending on the method, and onto conveyors for dewatering and drying. The open-pan process produces a flake-shaped crystal rather than the typical cubic form. Flake salt is preferred to produce cheese, butter, and baked goods. The Alberger process is a modified open-pan technique that produces flake salt that possesses a hopper shape in complete crystals.

Five companies operated 19 vacuum-pan salt plants, accounting for 10% of total U.S. salt production in 2002. Vacuum pan salt is produced in California, Kansas, Louisiana, Michigan, New York, Ohio, and Texas.

Processing

After rock salt is mined and solar salt is harvested, the material undergoes some basic mechanical processing that usually consists of crushing and screening to reduce and separate the particles into different marketable size fractions. Rock salt mines have underground stations consisting of a combination of primary crusher and feeder units that load the salt onto conveyor belts for transport to secondary crushers elsewhere in the mine. Some mines have underground screening equipment to size the fragments; other operations conduct the screening at the surface. After screening, the salt is shipped to either underground or surface storage bins, each containing a different size fraction. From this point, the salt is ready for packaging and shipping or loading as bulk salt into railcars, trucks, barges, or ships.

Solar salt processing consists of hauling the salt to wash plants or directly to a stockpile. There are different variations of wash plants, but they should be designed to fit the local conditions and quality requirements. After solar salt is dumped into a pit at a typical wash plant, the salt is fed to a vibrating feeder or screw conveyor where it gets washed with saturated salt brine to minimize dissolving the salt crystals. Depending on the amount of surface insolubles or occluded dirt and debris, the use of seawater or dilute brine is often implemented. The washed salt goes to a classifier and then on for dewatering before being conveyed to a storage site. Some solar salt operations dry the salt in rotary dryers and screen the salt before

sending it to the stock pile. Others do some wet screening but allow the wet salt to drain in large windrows for periods not less than 2 weeks but up to several months before shipping.

Vacuum-pan process salt is produced by heating salt brine in large vertical evaporators. This processing method is usually applied to green brines formed from the solution mining method. Three to five evaporators are placed in series with each one in line under a greater vacuum than the preceding one. A unit consisting of three evaporators is also known as a triple-effect evaporator system. When pressure is lowered in an evaporator, the temperature at which water will boil also is reduced. Steam is fed to the first pan causing the brine to boil. The steam liberated by the boiling brine is used to heat the brine in the second pan. The pressure in the second pan is less, thereby allowing the steam made by the boiling action in the first pan to boil the brine in the second evaporator. The pressure continues to be reduced in each succeeding evaporator. Although the boiling process could be done using only one vacuum pan, more salt can be made per pound of steam using several pans in a row, and this multiple-effect process saves energy.

Brine processing can also consist of removing the majority of dissolved impurities from the salt in the solution. Calcium and magnesium are two common ions associated with salt that are precipitated and removed during brine purification treatment. Soda ash, also known as sodium carbonate, is used to remove calcium ions, which precipitates as calcium carbonate. Magnesium ions are precipitated and removed by adding caustic soda or lime. The resulting precipitates—magnesium hydroxide or magnesium carbonate—finally settle out along with the calcium carbonate. Barium carbonate is used to remove calcium sulfate from brines by forming insoluble barium sulfate. Sometimes hydrogen sulfide is dissolved in the brine but can be eliminated by reacting it with sulfuric acid to produce the gaseous oxides of sulfur and neutralizing the acid with lime. Once the salt has been purified, bringing the purity level above 99.9% sodium chloride, the salt is dried in either a rotary dryer or a fluid-bed dryer to keep the salt from caking during the drying process. If anticaking agents such as yellow prussiate of soda are added, they are added before drying. Free-flowing additives or other additives are added to the dry salt in mixing conveyors before storage or packaging.

A similar type of process called a recrystallizer process has been applied to solid salts, such as solar and rock, but is not as energy efficient and thus has lost popularity with processors. Solid salt requires dissolving before applying the recrystallization process.

Product Forms

Salt is marketed and shipped in various forms, the most common being bulk. Most large chemical and industrial salt consumers buy in bulk quantities to reduce costs. Bulk salt purchasers should have adequate storage space to accommodate the volume of material purchased. Bulk shipping costs are usually less than those for packaged salt.

Packaged salt consists of salt sold in round cans, boxes, shakers, single-serve packets, kraft paper bags with polyethylene film liners, or plastic bags. Big bags or super sacks, holding up to a ton of salt, are used as a means of shipping a small bulk quantity. These bags can be palletized for easy handling by forklift. Many purchasers use these containers to deliver pre-weighed quantities of bulk salt to their batch processes. Whatever the container size, most packaged products are sold and shipped as unitized pallet quantities. Most vacuum pan salt for human consumption is packaged in one or more type of container. Because of the packaging and handling costs, the unit price is higher than for bulk salt. The majority of packaged salt is sold through grocery, food service, institutional, and related outlets, or to food processors or manufacturers.

Pressed blocks include large salt bricks, spools, smaller bricks, pellets or “pillows,” and other compressed forms used by the water conditioning and agricultural sectors. Fifty-pound blocks are the most common pressed block sold. Very high hydraulic pressures are used to press the salt blocks. Blocks sold for animal nutrition often have trace minerals added to them, based on veterinary advice, to supplement what is missing from the normal diet of the animal. Because of an animal’s natural craving for salt, this method of nutrient supplementation works well to deliver just the right amount without overfeeding.

Pellets and pillows are briquetted e-shaped pieces of salt that have been compressed for ease of handling, reduced mashing, and slower dissolution rate. Most compressed salt products are for water softening applications. Although no longer commonplace, salt tablets were sold as compressed pellets and used to replace lost minerals during excessive fluid loss such as sweating and for canning applications.

Additives

Temperature and moisture (even as humidity) affect salt in storage or in use. For these reasons, free-flowing agents are added to help the salt pour freely. The agent should have very good adsorptive, covering, and adhesion properties; be food grade and nontoxic, odorless, colorless, dustless, tasteless, inexpensive, and soluble enough or fine enough to show no sediment in brine (Kaufmann 1960). For example, the agent also should not cover the salt grain so completely as to slow up the recognition of the salt taste when preparing food, and it should keep deicing salt, used for melting ice and snow, free flowing.

Between 0.5% to 1.0% of free-flowing additives are normally added to table salt. The agents could include sodium silicoaluminate, magnesium carbonate, calcium silicate, di- or tricalcium phosphate, and calcium carbonate.

Salt is an excellent carrier of potassium iodide or potassium iodate, which are used to prevent iodine deficiency disorders (IDD) in humans. Nearly one billion people are at risk of contracting IDD throughout the world, mainly in the underdeveloped nations. IDD includes several abnormalities, such as goiters, mental retardation, deaf mutism, squint, difficulty standing and walking, and stunted limbs. Without treating the population by simply using iodized salt, the social and economic progress of countries becomes adversely affected. The cost to prevent IDD is \$0.05 per person per year. The International Council for Control of Iodine Deficiency Disorders, the United Nations Children’s Fund, the Micronutrient Initiative, and the Salt Institute have joined together as the Network for the Sustained Elimination of Iodine Deficiency, the umbrella group coordinating the global effort to overcome this international, treatable problem. In developed countries, iodized salt contains 0.01% potassium iodide, with 0.2% of a stabilizing mixture of sodium thiosulfate and calcium hydrate or dextrose and sodium bicarbonate. Where iodine stability may be an issue, potassium iodate is used globally for both animals and for humans.

Specifications

Salt is sold to various end-use markets with specific chemical and physical specifications formulated by reputable scientific agencies and/or medical organizations, or on niche specifications established for particular branded products by the producing companies. The specifications are important to ensure that consumers are obtaining a safe, consistent, and reliable grade of salt for their requirements. The specifications of salt for human consumption are different than those for highway deicing. The purity and quality of salt also varies

Table 3. Specifications applying to the salt industry

Type Specification	Title	Designation	Jurisdiction
Analysis	Standard Methods for Chemical Analysis of Sodium Chloride	ASTM-E-534-98 (2003)	American Society for Testing and Materials

Adapted from the Salt Institute 2005.

depending on the type of salt; rock salt is generally less pure than more refined vacuum pan salt. Table 3 lists the specifications that apply to salt sold in the United States.

USES

World salt use is equal to world salt production, assuming that inventories on a global basis are discounted. Therefore, the total quantity of salt used in the world in 2002 was 210 Mt.

The pattern of end-use markets is very similar among developed nations in the world with the chemical industry as the largest international consumer of salt. Most markets are mature and show minimal growth rates for salt usage. Less developed countries tend to use more salt for human and agricultural applications. Table 4 lists the trends of the top 10 salt-producing countries of the world since 1990. Salt use in general in the United States has increased during the past 200 years. Various events have affected domestic per capita salt usage. Before the beginnings of the chemical industry in the United States in about 1884, most of the salt used was for food and animal hide preservation and in refrigeration.

New chemicals made from salt and new applications using salt contributed to a significant increase in salt use during the early twentieth century. It should be noted that the chemical and highway deicing sectors were responsible for the greatest increases in salt usage.

There are more than 14,000 direct and indirect uses of salt—it would be virtually impossible to collect data for all of them. The U.S. Geological Survey and the Salt Institute, the trade association of the North American salt industry, survey end-use consumption information on 28 individual uses in eight major categories that include chemical, food processing, general industrial, agricultural, water treatment, ice control, distributors, and miscellaneous. These industries are the first-tier consumers of salt; information on most of the other downstream customers (such as who the distributors sell salt to) is unavailable. Changes in the quantity of salt consumed by the chemical industry and for highway deicing changed substantially during the twentieth century. Highway deicing salt usage has

Table 4. World salt production (1990–2002), kt

* Estimated value.

been controlled mainly through “Sensible Salting” techniques recommended by the Salt Institute, and training seminars that educate workers to spread highway salt judiciously and effectively. The result is achieving dry pavement using the least amount of salt per storm, thus protecting the environment from excess salt brine runoff and cost-effectiveness.

Chemical Industry

The U.S. chemical industry is the largest consumer of salt, representing 45% of reported consumption in 2002. This category is distinguished by two important categories: the chloralkali industry and other chemical manufacturers.

Chloralkali

The chloralkali industry is the largest segment of the chemical sector that uses salt. Traditionally, this end use included salt consumed for chlorine, coproduct sodium hydroxide (also known as caustic soda and lye), and synthetic soda ash; however, since 1986, no synthetic soda ash has been manufactured in the United States. Outside the United States, many manufacturers continue to use salt for synthetic soda ash production.

Salt is used as the primary raw material in chlorine manufacture because it is the chief source of chlorine ions. For sodium hydroxide production, salt is the main source of sodium ions. Approximately 98% of domestic chlorine and sodium hydroxide produced are obtained from the electrolysis of salt brine feedstock using three different cell technologies: (1) diaphragm, 78%; (2) mercury, 14%; and (3) membrane, 6%. It takes about 1.59 t of salt to make 0.9 t of chlorine and 1 t of coproduct caustic soda. The electrolytic process splits sodium chloride into ions that selectively pass through special membranes. Chlorine gas forms at the anode while sodium ions migrate through the membranes toward the cathode where sodium hydroxide forms and hydrogen gas evolves. In 2002, 10.3 Mt of chlorine and 8.2 Mt of caustic soda were produced in the United States.

Making synthetic soda ash had been the primary method for obtaining soda ash in the United States until 1971, when natural soda ash production exceeded that of synthetic. The main process for making soda ash was the Solvay process, developed in the early 1860s. Today, it is still the main technique used by the rest of the world. Carbon dioxide gas is percolated through a carbonation tower containing nearly saturated salt brine to which ammonia has been added. Ammonium bicarbonate forms, which reacts with the brine to form sodium bicarbonate and ammonium chloride. The sodium bicarbonate precipitate is collected, filtered, and calcined into soda ash. Residual sodium chloride is discharged as plant effluent. The chloralkali subsector is classified under Standard Industrial Classification (SIC) code 2812 and since 1997, under the North American Industry Classification System (NAICS) code 325181.

Other Chemicals

The other subsector that uses salt includes chemical establishments that make sodium chlorate, metallic sodium, and other downstream chemical operations that use salt as a feedstock. In powdered soaps and detergents, salt is used as a bulking agent, and as a coagulant for colloidal dispersion after saponification. In pharmaceuticals, salt is a chemical reagent, and it is used as the electrolyte in saline solutions. Additionally, it is the base ingredient for hemodialysis fluids and is used as a polishing agent for pharmaceutical tablets and caplets. Salt is used as a cofeedstock with sulfuric acid to produce sodium sulfate and hydrochloric acid. This subsector is relatively small, comprising only 10% of domestic salt sales for the entire chemical sector and only 4% of total domestic salt consumption. These chemicals are classified under SIC 2899 (NAICS 3251998), excluding SIC 2812 (NAICS 325181)—alkalis and chlorine.

Food Processing Industry

Although every person uses some quantity of salt in their food, the entire category only represented 4% of reported usage in 2002. Salt is added to food as a flavor enhancer, preservative, binder, fermentation control additive, texture aid, and color developer. This major category is subdivided into six subsectors, in descending order of salt consumption: meat packers, canning, other food processing, baking, dairy, and grain mill products. Additional salt for human consumption is also included in grocery wholesalers. It is estimated that about

75% of the grocery store category is salt for food processing; the remainder is for other household applications.

Meat Packers

Salt added to processed meats promotes the color development in bacon, ham, and other processed meat products. As a preservative, salt inhibits the growth of bacteria, which would lead to product spoilage. Salt acts as a binder in sausages, forming a binding gel comprised of meat, fat, and moisture. Salt also acts as a flavor enhancer and a tenderizer. This subsector is engaged in slaughtering and processing meat and poultry products and in sausage and other prepared meat manufacturing. It includes SIC codes 2011, 2013, and 2016, with their corresponding NAICS codes, 311611, 311612, and 311615.

Canning

Salt is primarily added to the canning process as a flavor enhancer and preservative. It also is used as a dehydrating agent, tenderizer, enzyme inhibitor, and as a carrier for other ingredients. Establishments that can vegetables, vegetable juices, jams, jellies, pickled fruits, and specialty products such as baby foods and seafood are in this category. It includes SIC 2032, 2033, 2034, 2035, and 2091. The NAICS codes for these products are 311422, 311999, 311421, and 311941.

Other Food Processing

Salt is used mainly as a seasoning agent, adding flavor to food in this end use. Other food processing includes miscellaneous manufacturers that make food for human consumption (i.e., potato chips, pretzels, and other snack food items) and domestic pet consumption (i.e., dog and cat food). They are included in SIC 206, 207, 208, 2047, 2099, and any other food category not included in the aforementioned SIC codes. NAICS codes correspond with 311111, 111998, 31134, 311911, 311423, 311991, 31183, 311823, and 311999.

Baking

Salt is added to control the rate of fermentation in bread dough. Additionally, it is used to strengthen the gluten (the elastic protein-water complex in certain doughs) and as a flavor enhancer, such as a topping on baked goods. This subsector includes companies making bread, cakes, cookies, and other perishable bakery products. It includes SIC codes 205, 2051, and 2052. The NAICS equivalents are 311812, 311821, and 311919.

Dairy

Salt is added to cheese as a fermentation control agent and as a color and texture control agent. The dairy subsector includes companies that manufacture creamery butter, natural and processed cheese, condensed and evaporated milk, ice cream, frozen desserts, and specialty dairy products. It incorporates SIC codes 202, 2021, 2022, 2023, 2024, and 2026. NAICS codes are 311512, 311513, 31152, 311514, and 311511.

Grain Mill Products

This group includes establishments engaged in milling flour and rice, and manufacturing cereal breakfast foods, and blended or prepared flour. SIC codes are 204 (excluding 2047), 2041, 2043, 2044, and 2045. NAICS codes are 311211, 31192, 31123, 311212, and 311822.

General Industrial

The industrial uses of salt are diverse. This major sector of salt consumption includes, in descending order of salt usage: oil and gas exploration where salt is used in the drilling process, metal

processing, other industrial, pulp and paper, textiles and dyeing, tanning and leather treatment, and rubber manufacture. General industrial applications accounted for 6% of 2002's total reported salt usage. The numbers are in decline in the United States because many of these manufacturing industries are moving overseas.

Oil and Gas Exploration

Salt is an important component of drilling fluids used in well drilling. It is used as a flocculent and as a compound to increase drilling fluid density to overcome high down-well gas pressures. Whenever drilling activities encounter salt formations, salt is added to the drilling fluid to saturate the solution and minimize the dissolution within the salt strata. Salt is also used to increase the set rate of concrete in cement casings. This SIC category includes companies engaged in oil, gas, crude petroleum, and refining and compounding lubricating oil. It includes SIC major groups 13 and 29. NAICS codes are 211111, 213112, and 336611.

Metal Processing

Salt is used in concentrating uranium ore into uranium oxide, or yellow cake. It is also used in processing aluminum, beryllium, copper, steel, and vanadium. Establishments engaged in the smelting, refining, and fabrication of ferrous and nonferrous metals represent this category, which includes SIC 33, 34, 35, and 37. NAICS equivalents are 422690, 333994, and 213114.

Other Industrial

This subsector is represented by any group not included in any of the general industrial groups in this major category.

Pulp and Paper

Salt is used to bleach wood pulp. It also is used to make sodium chlorate, which is added with sulfuric acid and water to manufacture chlorine dioxide—an excellent oxygen-based bleaching chemical. Although the chlorine dioxide process originated in Germany after World War I, it has become more popular because of environmental pressures to reduce or eliminate chlorinated bleaching compounds. Companies that manufacture wood pulp, cellulose fibers, pulp from rags, paper and paperboard, and paper and paperboard converted products are included in this subgroup, which includes SIC group 24 and NAICS groups 322121, 322130, and 322122.

Textiles and Dyeing

In commercial dye manufacture, salt is used as a brine rinse to separate organic contaminants, promote “salting out” of dyestuff precipitates, and blending with dyes to standardize concentrated dyes. One main role for sodium chloride is to act as a mordant (color fixer); that is, to provide the positive ion charge to promote the absorption of negatively charged dye ions. The textile and dyeing industry includes businesses involved in fiber preparation and subsequent yarn and woven fabrics manufacturing, and fiber dyeing and finishing. This includes SIC group 22 and also NAICS 313311.

Tanning and Leather Treatment

Salt is added to animal hides to inhibit bacterial decomposition on the underside of the hides, to remove some of the moisture in the hides, and to remove some of the blood. This process is called “curing” (Kaufmann 1960). This subsector includes establishments that cure and/or tan animal hides. It includes SIC 311 or NAICS 316110.

Rubber Manufacture

Salt is used to make neoprene rubber, white rubber, and Buna rubber. Salt brine and sulfuric acid are used to coagulate emulsified latex made from chlorinated butadiene. Businesses that make rubber

and rubber products, such as synthetic rubber, tires and inner tubes, rubber and plastic footwear, reclaimed rubber, rubber and plastic hose and belting, and other fabricated rubber products, comprise this category. It includes SIC codes 282, 2, 30 (excluding 3079), 3011, 3021, 3031, 3041, and 3069. The NAICS corresponding numbers are 325212, 326211, 316211, and 31332.

Agricultural Industry

Since prehistoric times, humans have noticed that animals satisfied their salt hunger by locating salt springs, salt licks, or playa lake salt crusts. Barnyard and grazing livestock need supplementary salt rations to maintain proper nutrition. Veterinarians have advocated adding salt in commercially mixed feeds or in block forms, which are sold to farmers and ranchers. Salt also acts as an excellent carrier for trace elements not found in the vegetation consumed by grazing livestock. Sulfur, selenium, and other essential elements are commonly added to salt licks, or salt blocks, for free-choice feeding.

The agricultural end-use sector contains three subgroups—feed retailers and/or dealers and mixers, feed manufacturers, and direct buying end users. The entire category represents 4% of total reported usage in 2002, even when including agricultural distribution (contained under “distributors”).

Feed Retailers/Dealers/Retailers-Mixers

Establishments engaged in the retail distribution of animal feeds, fertilizers, agricultural chemicals, pesticides, seeds, and other farm supplies represent this subgroup. It incorporates feed retailers who mix on-site some or all of the feed they sell and whose primary customers are feed end users, not other feed retailers. There are no suitable SIC classifications for this subsector, but the NAICS codes are 311111 and 311119.

Feed Manufacturers

This subcategory includes establishments engaged in preparing feeds and feed ingredients and adjuncts for animals and fowl, including poultry and livestock feed and feed ingredients such as feed supplements and concentrates and premixes. It does not include the local dealer-mixer, whose primary business is reselling prepackaged feed and feed ingredients to end users, but who does a moderate amount of custom mixing secondarily. The end use includes SIC 2048 and NAICS 311611.

Direct-Buying End Users

Salt used in this subsector is for consumption by farms, ranches, dairies, feed lots, and so forth, buying on a direct basis from salt producers. It includes SIC major group 2. Also, this would include NAICS 112000 series.

Agricultural Distribution

This subcategory of “distributors” is a secondary, or second-tier, consumer of salt, and includes companies involved in the wholesale distribution of animal feed products, fertilizers, agricultural chemicals, pesticides, seeds, and other farm supplies to retail feed dealers and some large end users who buy on a wholesale basis. It includes co-op (except mixing operations) and independent wholesalers/distributors. SIC 5159 is the category classification. The corresponding NAICS code is 42259.

Water Treatment

Approximately 1.2 trillion L (0.3 trillion gal) of water are used daily in the United States for residential and commercial use. Many areas of the United States have “hard” water, containing

excessive calcium and magnesium that contribute to buildup of a scale or film of alkaline mineral deposits in household and industrial equipment. Commercial and residential water softening units use salt to regenerate inactive sites on ion-exchange resin beds that work to soften water by removing the ions causing water hardness. Typical hardness ions, calcium and magnesium, are removed from water sources by passing the water supply through an ion-exchange resin bed where they exchange places with sodium ions that reside within the resin. Once depleted, flushing with salt brine recharges the resin bed. The sodium ions from the brine are exchanged for calcium and magnesium that have been in sites on the resin bed. In 2003, water treatment represented 4% of total domestic reported usage. During the past 10 years, potassium chloride has become increasingly popular for regenerating home water softener systems. Sodium chloride, however, is still the most popular regenerant on the market.

Since the turn of the twenty-first century, some municipalities have begun to restrict the use of water softeners claiming that the discharge from home softeners increases the total dissolved solids that impact municipal water treatment systems. This restriction has been most prevalent in some areas of Southern California where water reclamation is of considerable concern.

Government and commercial water treatment are the primary subgroupings of water treatment; and water treatment distribution is the secondary subgroup, which is the second-tier market for salt sales.

Government

This subsector includes local, state, and federal customers purchasing directly from salt producers for water treatment usage. It includes SIC 2899 and the corresponding NAICS code, 422690.

Commercial

All commercial establishments that purchase salt primarily for water treatment, and not classified elsewhere, are in this category. It includes car washes, laundries, and utilities. It is included in SIC 2899 and NAICS code 421720.

Water Treatment Distributors

Water-conditioning salt-route operators and distributors whose exclusive or dominant business is distributing water conditioning products to home or industry represent this subcategory. It is included in SIC 7399 or NAICS 221310.

Ice Control and Road Stabilization

The second largest end use of salt in North America and Europe is for highway deicing. Salt has been used to melt snow and ice on roadways for the past 60 years. Gabriel Daniel Fahrenheit, the developer of the Fahrenheit temperature scale, discovered that salt mixed with ice (at a temperature below the freezing point) creates a solution with a lower freezing point than water itself. When salt is applied to an ice-covered road, it bores through the ice, melting as it proceeds, and forms brine as it mixes with the melted liquid from the ice. The brine collects below the surface of the ice and snow and prevents the water from refreezing into ice and bonding to the road surface. The phase diagram (see Figure 5) for sodium chloride demonstrates the freezing point depression of brine, as opposed to plain water, along with the different phases of solid and liquid brine. The manner in which brine freezes depends on the initial strength of the brine. It is sometimes mistakenly assumed that the stronger the brine, the lower the temperature at which freezing begins. This is true only for brine strengths up to 23.31% by weight of sodium chloride. These issues are critical to the proper use of Sensible Salting techniques recommended by the Salt Institute.

Figure 5. Phase diagram for sodium chloride water freezing point depression

Adapted from the Salt Institute 2004.

* Links to the methodology and downloadable one-page summaries for each state and province are found at <http://www.saltinstitute.org/30.html>.

The public in a dynamic society demands that governments keep commerce mobile by keeping traffic arteries open during winter snowfalls. A 2004 study by the economic consulting firm Global Insight Inc. (Waltham, Massachusetts) found enormous costs associated with blizzards that might shut down various states and provinces. The results of the study are shown in Table 5. The public also expects traffic accidents to be minimized. Salt is an inexpensive, widely available, and effective ice control agent to meet the demands. It does, however, become less effective as the temperature decreases below -21.2°C (-6.0°F). At lower temperatures, more salt would have to be applied to maintain higher brine concentrations to provide the same degree of melting. Most winter snowstorms and ice storms occur between -6°C (20°F) and 0°C (32°F), a range in which salt is most effective.

Source: Johnson 2000.

Since about 1994, there has been increasing use of pre-wetted salt and anti-icing techniques to improve the ability to gain a “bare pavement” road condition as quickly, safely, and as cost-effectively as possible, while still meeting the needs of the affected communities. Studies have documented the vital economic role of clearing ice and snow from roadways. Ice and snow also cause higher fuel costs as cars lose traction because of lower tire friction and spin their wheels to travel a given distance. A car that under normal weather conditions gets 25 mpg may get only 15 mpg on a slippery road (Hanalby 1994).

In addition, salt is added to stabilize the soil and provide firmness on which highways are built. The salt acts to minimize the effects of shifting brought about by changes in humidity and traffic load in the subsurface.

In highway deicing, salt has been associated with corrosion of motor vehicles, bridge decks, unprotected steel structures, and reinforcement bar and wire used in road construction. The automobile industry has made great strides in reducing the most costly impact from using deicing salt. Manufacturers have been successful in engineering corrosion resistance into their vehicles through better design and use of noncorrosive materials, such as fiberglass and plastics. The use of noncorrosive materials has lowered corrosion perforations significantly. The ages of passenger vehicles on the road has shown an upward trend for the past 20 to 25 years. This has allowed vehicle manufacturers to provide corrosion perforation warranties of up to 12 years for some model vehicles (see Table 6 and Figure 6). According to Rendahl (1998), “...some models nearly manage to avoid corrosion completely, by a combination of improved construction and materials, together with a careful application of anti-rust agent and adhesives, penetrating and covering crevice surfaces.”

Surface runoff, vehicle spraying, and windblown actions can also affect roadside vegetation, soil, and local surface and groundwater supplies. Although there is evidence of some environmental salt loading during peak usage, the spring rains and thaws usually

Source: Johnson 2000.

Figure 6. Average mean and median ages of passenger vehicles from 1970 to 1994

provide sufficient water to dilute the concentrations of sodium in the area. Adverse environmental action can also be controlled and minimized by effective spreading techniques recommended by the National Local Technical Assistance Program Association and by the Salt Institute.

The deicing category includes government (state, federal, and local) and commercial subsectors of consumption. Approximately 31% of total reported consumption was used in this category during 2002.

Government Deicing

More than 95% of this major category is for usage by separate local, state, and federal agencies to ensure safe and navigable roads during adverse climatic conditions.

Commercial Deicing

This subsector includes companies that purchase salt for ice control, such as transportation companies, shopping centers, ice control service contractors, and so forth. It includes any distributors whose primary or exclusive business is the distribution of salt for ice control purposes to business and/or government. It does not include institutional purchasers. There are no suitable SIC/NAICS codes for this section.

Other Uses of Salt

The other uses of salt include any consumer that is not included in any of the aforementioned categories. It also includes sales by distributors, excluding those by agricultural and water conditioning distributors that are included as subgroups under agriculture and water treatment. It includes part of grocery wholesale and retail, institutional whole sale distributors, U.S. government resale, and other wholesalers/retailers.

Institutional Wholesale Distributors

This subcategory includes companies engaged in the distribution of food and other salt products to restaurants, hospitals, schools, and other institutional establishments. These are included in SIC groups 58 and 70 and correspondingly, NAICS 722 series.

U.S. Government Resale

Included in this category are government units such as military commissaries that purchase salt for resale to armed forces personnel and dependents at the retail level. It also includes purchases by the government of food-grade salt used by armed forces/government food-services facilities, as well as all other government salt purchases not classified elsewhere. SIC 9199 or NAICS 92119 pertains to this subgroup.

Other Wholesale and Retail

This subsector includes wholesalers, not included elsewhere, primarily engaged in distributing merchandise for personal and household consumption to retailers, such as hardware stores, home centers, filling stations, and discount centers. It also includes all retail outlets that sell merchandise for personal or household consumption that purchase directly from salt producers. The SIC category is 5251, while the NAICS number is 44413.

ECONOMIC FACTORS

Prices

The price of salt depends on the type of salt, production location, product form, and nature of sale. Salt brine is the least expensive type of salt because it is not expensive to produce and processing is minimal. Vacuum pan salt is the most expensive because of the energy input and degree of final-product purity. The price of salt also can vary because of regional differences in labor rates, energy costs, packaging, transportation, and other operating factors. Large consumers of salt generally prefer to purchase salt in bulk quantities. When salt is packaged in bags, cylinders, or single-serve packets, or sold in compressed pellets or pressed blocks, the sales price increases compared with the bulk price. The price of salt can also vary if the consumer is buying based on bid contracts or spot purchases.

Foreign Trade

Salt is one of the largest internationally traded mineral commodities in the world. The estimated total world salt trade in 2002 is about 15% of total world salt production. Because salt is a low-valued material, it is uneconomic to transport long distances, particularly

over land. Overland transportation rates often are more expensive than ocean freight rates; therefore, some countries tend to import salt to certain regions where rail or truck rates from domestic salt production sites are cost-prohibitive.

Imports

Some countries import salt to satisfy demand requirements when indigenous salt resources are minimal or production capacity is inadequate. Japan is an example of a nation that imports the majority of its salt because it does not have any rock salt deposits. Climate and lack of available coastal land are not favorable for solar salt production. Other countries import salt because of economics. Although the United States is the largest salt producer in the world, it imported almost twelve times what it exported in 2002. Less expensive labor costs, transportation costs, and currency exchange rates are the main cost considerations for importing large quantities of salt into the United States. Most salt imported into the United States comes from Canada, Chile, the Caribbean, and Mexico. This salt is mainly consumed by the chemical industry or as deicing salt in areas of the country where there are no local salt deposits, such as the Pacific Northwest and the Southeast. The majority of salt imports are in bulk form, but there is also some imported product packaged in bags, sacks, barrels, and other forms. Before 1989, all imported salt was classified under the Tariff Schedule of the United States (TSUS), Annotated. The TSUS codes for salt in brine, bulk salt, and other salt were numbers 4209200, 4209400, and 4209600, respectively. Beginning in 1989, after the passage of the Omnibus Trade and Competitiveness Act of 1988, the United States adopted the internationally used Harmonized Tariff System (HTS) that aggregated the three classifications into one named "Salt (including table and denatured salt) and pure sodium chloride, whether or not in aqueous solution, sea water." This HTS code number is 2501.00.0000. Table 7 lists some of the recent U.S. import statistics.

Exports

Canadian exports to the United States make up the majority of foreign salt imports; however, the majority of U.S. salt exports are to the Canadian provinces of Ontario and Quebec. Canada represents about 87% of total U.S. exports. The remainder of export sales is small shipments mainly to other countries in the Western Hemisphere. Table 7 lists the trend in U.S. salt exports since 1970 (USGS 2004).

Transportation and Storage

Overland and waterborne transportation rates of salt are important economic factors to salt consumers. Transportation charges generally are always higher than the sales price of the salt being carried. Rock salt, solar salt, and vacuum pan salt are shipped in bulk or in some packaged form, such as shrink-wrapped bags on pallets, and 1-t "big bags." Because salt brine is a solution, it is transported through underground or surface pipelines.

Overland

Overland movements include salt moved by rail, truck, and pipeline from salt production localities to regional consumers. Because overland transportation rates are more costly than the salt, it is typically not economical to ship salt overland farther than about a 500-km (311-mi) radius from the production site. Competition from other salt producers is usually encountered at distances beyond that radius.

Rail Movement. Boxcars are used to convey packaged salt loaded on pallets. Forklifts and conveyor belts assist the loading of the salt into the boxcars. The majority of all railcars used to transport bulk salt are covered hopper cars. The protected cars prevent

Table 7. U.S. imports and exports of salt, kt

Year	Primary Production	Imports	Exports	Apparent Usage	Unit Value, \$/t	Unit Value, 98\$/t	World Production

inclement weather from affecting the salt. To avoid caking resulting from moisture and humidity, deicing salt is treated with 40–60 ppm of ferric ferrocyanide (known as Prussian Blue) or sodium ferrocyanide (yellow prussiate of soda, or YPS).

To reduce freight rates, most producers ship in unit trains that contain up to 12 railcars. The loading and unloading of covered hopper cars includes pneumatic equipment using flexible hoses and pipes. Many cars are equipped with bottom-dump doors or gates that allow faster unloading. Conveyors beneath the railcars take the salt to truck-transfer stations or to warehouses or stockpiles.

Truck Movement. Trucks are used in shorter hauls from production sites to customers' locations, or from distribution centers and warehouses to consumers. Bulk salt is carried in dump trucks or specially built pneumatic and tank trucks. Dump trucks can drop their loads directly into hoppers or onto a surface pad so that the salt can be picked up by front-end loaders. Open trucks should be covered properly with tarps to prevent caking or salt losses from being blown or shaken off the vehicle. Dump trucks can also unload into pits, which are convenient for companies that convert dry salt into brine.

Pipeline. Some salt brine is transported by pipeline between production sites and consumers' locations. The chemical industry is the largest consumer of brine, but some chloralkali operations are not located adjacent to salt deposits that could be solution mined. Several chemical companies in Louisiana and New York rely on brine supply companies to provide a continual supply of brine feedstock. Some of the pipelines are only a couple of kilometers in length; however, others can be up to 100.0 km (62.1 mi) long or more.

Waterborne

Waterborne movements of salt include salt shipped in barges and freighters. This type of transportation is the most economical method to move salt great distances. Although rock salt and solar salt are the two major types of salt shipped on the water, bulk vacuum pan salt from the Netherlands is also shipped on water to various locations, including the southeastern United States.

Barge. The Erie Canal and the Chesapeake & Ohio Canal owe part of their origin to the early salt industry of the eastern United States. Barges were the easiest way to transport salt and other goods to customers far away. Barges are used today in shipping salt along the Intracoastal Waterway of the Gulf Coast, up the Mississippi River to other rivers, such as the Ohio, and to the Great Lake ports, the Florida coast, and inland waterways. They are also

used to transport salt across the Great Lakes to and from Canada, and from Mexico to the Pacific Northwest. Several barges are linked together and towed inexpensively to distant locations. When freezing winter conditions in the Midwest affect the major rivers and their tributaries, salt movements by barge cease until the ice is broken or thaws. Low water levels on the Mississippi River have, on occasion, halted barge traffic for weeks at a time.

Salt is usually loaded onto barges using conveyor belts with moveable swing arms to evenly distribute the salt in the hold. A conveyor system is also found in the bottom holds of many barges to unload the salt at the final destination. Barge-mounted or shore-mounted cranes with clamshell buckets are also used to unload salt.

Freighter. Bulk freighters are the dominant method of transporting waterborne salt throughout the world. Salt may represent a partial cargo or the entire cargo on a ship. When the Jamestown and Plymouth colonial settlers arrived in the New World, imported salt was carried as ballast in the hulls of sailing ships arriving from England. Today, modern bulk freighters may range in size from 6 to more than 90.7 kt (100 thousand st).

Some freighters have self-unloading equipment to discharge the salt from the cargo hold. The most common method of unloading bulk salt is by clamshell bucket and crane. The ship is brought alongside the dock and the salt is transferred to a dockside storage site or to a transportation system.

Storage

Bulk salt may be stored outside on specially engineered pads that reduce the amount of runoff that threatens surface and groundwater. The storage sites are usually located near areas accessible by water, rail, or truck. Salt is stored in conical-shaped piles or long windrows. Plastic, canvass, or burlap covers are often used to protect the salt from the wind and rain. These tarps are secured by adding weights or heavy tires to keep them from blowing off.

Inside storage bins, silos, and warehouses are also used to store bulk salt. For convenience, the site is usually located near the rail, truck, or ship loading facilities. Packaged salt is often stored in warehouses adjacent to where the salt is bagged or containerized. Some manufacturers will lease warehouse space near active markets that are located at some distance from their plants.

ENVIRONMENTAL AND HEALTH CONSIDERATIONS

Since the early 1970s, people throughout the world have become more conscious about the environmental effects of pollution caused

by industrialized societies. In pursuit of better living conditions and longer life spans, many people have changed their lifestyles based on advice found in literature and publicized in the media. These topics have a bearing on salt consumption, and therefore, salt demand.

The national energy crisis that began in 1973 adversely affected several energy-intensive industries, one being the synthetic soda ash industry that used tremendous quantities of salt. Higher energy costs, environmental problems pertaining to discharges of sodium chloride and calcium chloride to groundwater supplies, and competition from natural soda ash sources contributed to the closure by 1979 of seven of the eight synthetic soda ash plants that operated during the 1970s. The last plant closed in 1986, which ironically was the first plant constructed in 1881 and commenced production in 1884. The demise of this sector of the domestic chemical industry resulted in the significant loss of salt production.

In the highway-salt marketplace, the U.S. salt industry, through its membership in the Salt Institute, initiated a Sensible Salting Program in 1972 to educate transportation departments on proper ways to store, handle, and apply deicing salt to protect the environment while maintaining winter mobility and safety. The practice of knowing when to use salt, what alternative ice control agents to use, and how much salt to apply has contributed to improved environmental protection from overuse of salt. Deicing salt is the fastest, least expensive, and most effective agent to control the hazards associated with ice and snow. Without salt, there would be significant increases in the number of traffic accidents, loss of life, and productivity.

Population increases have caused increases in municipal waste treatment, resulting in elevated salinities in waterways. As individuals consume salt in their diets and in household activities, sodium and chloride are discharged to the environment through municipal sewage systems. The cities with growing populations are experiencing these increases. Although runoff from irrigated agriculture influences salinity, especially in the western United States, chloride trends are not appreciably correlated with changes in irrigated acreage nationwide.

In the late 1960s and early 1970s, health authorities attributed salt as one of the alleged causes of hypertension, or high blood pressure. People began restricting their salt intake and measuring the sodium levels in ingested food. It was not until the mid-1980s that other medical research suggested that other factors beside salt contributed to hypertension. In 1988, the U.S. Environmental Protection Agency (EPA) issued the National Primary Drinking Water Regulations that eliminated sodium as a regulated drinking water contaminant. The EPA rationale was that evidence was building that salt did not “cause” hypertension, and that the quantity of sodium in drinking water was very low compared with what is contained in food and other beverages.

Most ingested sodium comes from food, not beverages. Salt intake influences many bodily functions, the most discussed of which is blood pressure. For 4,000 years science has known that salt intakes can affect blood pressure through signals to the muscles of blood vessels trying to maintain blood pressure within a proper range. It is also accepted that a minority of the population can lower their blood pressure by restricting dietary salt. Elevated blood pressure, “hypertension,” is a well-documented risk factor for cardiovascular events such as heart attacks and strokes. It has been suggested that because salt intakes are related to blood pressure, and because cardiovascular risks are also related to blood pressure, that, surely, salt intake levels are related to cardiovascular risk. This is the “salt hypothesis” or “sodium hypothesis.” Data are needed to

confirm or reject this hypothesis. Until the 1990s, scientists had never tested the “salt hypothesis” by documenting whether reducing dietary salt actually reduces a person’s chances of having a heart attack or a stroke. As of 2004, there are ten “health outcomes” studies of sodium reduction. Not a single study has found an association in the general population between low-sodium diets and reduced incidence of cardiovascular events like stroke or heart attack. See www.saltinstitute.org/27.html for a list of the studies. It is also accepted that a minority of the population can lower blood pressure by restricting dietary salt.

Canada advises that only a minority of its population—those with high blood pressure or “high risk of developing high blood pressure” need concern themselves about the intake of sodium in their diet.

Official policy in the United States is for virtually everyone to reduce dietary salt. But conflicting recommendations exist even in the United States. The U.S. Preventive Services Task Force (2004, p. 634) states, for example:

There is insufficient evidence that, for the general population, reducing dietary sodium intake or increasing dietary intake of iron, beta-carotene, or other antioxidants results in improved health outcomes (“C” recommendation); recommendations to reduce sodium intake may be made on other grounds, including potential beneficial effects on blood pressure in salt sensitive persons.

The debate has confused the public, but there is a clear downward trend in consumer concern about dietary salt—tracking the new science. The International Food Information Council reported in early 2004 that only 5% of consumers are trying to avoid salt in their diets.

It is likely that new studies using the higher standards of evidence-based medicine will reduce the ongoing controversy, better inform public policy, and reduce consumer confusion.

FUTURE TRENDS

Despite the environmental concerns regarding deicing salt, rock salt will continue as the deicing agent of choice. Further improvements in technology for weather forecasting and instrumentation will allow calibrating technical application to actual ice-melting needs in ways not possible earlier. This will allow safer roads with less product usage. Other deicing products, such as calcium magnesium acetate, are commercially available but are more expensive, and more must be used to have the same effect as salt.

Human salt intakes are a function of population (intake levels are unchanged over the past century); thus continuing global increases are expected for the next 15 years. Because most markets for salt are mature, domestic and world consumption will grow proportional to the rise of population and the gross domestic product of countries.

The United States will remain the largest salt-producing nation in the world for years to come, though the rapid industrial growth in China may change its relative position in the coming decades. Since the middle of the twentieth century, the U.S. salt industry has restructured itself through acquisitions, name changes, and consolidations to become a more integrated North American industry competing in the Western Hemisphere.

The world will continue to mine, harvest, process, transport, and sell salt among neighboring countries. New deposits will be developed in the future that will probably compete with existing facilities. The facilities having the lowest production costs, offering a high-quality product, and having low transportation costs will be the leaders of the world salt industry.

ACKNOWLEDGMENTS

The author would like to acknowledge the help of Dennis S. Kostick, U.S. Geological Survey, Reston, Virginia, for his help with this edition and the groundwork he provided from the previous edition. Also, she acknowledges the support offered by J. Wallace Gwynn, Ph.D., Utah Geological Survey, Salt Lake City, Utah; and Richard L. Hanneman, Salt Institute. The author would like to thank her husband, Charles M. Feldman, Ph.D., for his editing and support.

Industrial Sand and Sandstone

Steven Herron

Industrial sand is a term normally applied to high-purity silica sand products with closely controlled sizing. It is a more precise product than common concrete sand and asphalt gravels. Although deposits of common construction sand and gravel are wide spread, industrial sand deposits are limited. The special properties of industrial sands—purity, grain size, color, inertness, hardness, and resistance to high temperatures—make them often irreplaceable in a variety of industrial applications. Their higher silica content allows for more specialized, higher margin applications than construction sand and gravel.

Industrial sand is found in many forms, colors, and grades. In general terms, the mineral quartz (SiO_2) is the predominant component of industrial sand. Although most industrial sand deposits contain a high percentage of quartz (95% plus), using industrial sands with lower quartz content is becoming more common as demand for industrial sand outpaces production in certain markets, particularly in the western United States.

Silica is found in most rock types of every geologic age and virtually everywhere in the world. Silica can be found in products that are used daily. From fiber-optic cables to beverage containers and insulation, it is difficult to imagine a world without silica-derived products.

The crystal structure of silicon dioxide consists of one atom of silicon bonded to four surrounding atoms of oxygen to form a three-dimensional network of SiO_4 tetrahedra. Approximately 64% of the crust of the earth (Klein and Hurlbut 1999) is composed of minerals built around a three-dimensional framework of linked SiO_4 tetrahedra. These minerals belong to the tectosilicate class in which all the oxygen ions in each SiO_4 tetrahedron are shared with neighboring tetrahedral. This results in a stable, strongly bonded structure in which the Si:O ratio is 1:2.

There are at least nine known polymorphs of SiO_2 , one of which is synthetic. Each polymorph has its own space group, cell dimensions, characteristic morphology, and lattice energy. The principal naturally occurring SiO_2 polymorphs fall into three structural categories: low quartz, low tridymite, and low cristobalite. This chapter focuses on industrial sands containing the low-quartz polymorph.

Quartz is characterized by its glassy luster, conchoidal fracture, and crystal form. A great many different types of quartz exist, to which varietal names have been given. Although the mineral quartz is common, deposits of high-quality industrial sand and

sandstone are rare. Most industrial sands that consumers prefer are products with a high percentage of pure quartz and corresponding low percentages of “contaminants” (e.g., accessory minerals). However, many consumers sacrifice quartz grade for other considerations such as color, price, and availability. A number of consumers evaluate competing products and accept lower grade industrial sand products.

USES AND SPECIFICATIONS

Industrial sand that is mined and beneficiated for industrial uses must meet or exceed specifications derived by the product end users. Specifications are as varied as the users, and often consider freight and availability. In the United States, the glass industry consumes approximately 40% (Dolley 2003) of all industrial sand production. Other relevant markets include foundry (approximately 20%), ground silica (PV), abrasives (approximately 5%), proppants (approximately 5%), filtration products, and recreation and building materials (including stuccos, thin sets, and grouts).

Glass and Ceramic Sand

Quartz is the principal glass-forming compound in a glass batch. Glass manufacturers enjoy some flexibility in chemical specifications; therefore, most specifications are indexed to the chemistry of certain deposits. These specifications (Tables 1 and 2) define the limits and ranges for chemical properties and size distribution that can be permitted in a specific furnace. Some specifications such as heavy mineral content or total iron oxide content (Mills 1983) are critical to a glass manufacturer and require stringent limits. Iron oxide is present in almost every raw material used in a glass batch and must be strictly controlled so that a consistent color is maintained in the finished product. Heavy minerals must also be strictly controlled. Because of the refractory nature of many heavy minerals (e.g., corundum, zircon, and ilmenite), they do not fully melt in the furnace, which results in stones or “feathers” in the finished products.

Glass-grade industrial sand can be sold into several markets within the glass market segment. Sand is used in the production of flat, container, fiber, and specialty glass products. Specialty glass consists of many products. The largest portion of the specialty glass business is laboratory and lighting glass (incandescent and fluorescent light bulbs). Specialty glass also includes components in the electronics industry such as optical fiber and semiconductors.

Glass-grade, whole-grain industrial sand is also sold into the ceramics market. Up to 32% of the ceramic body of sanitary ware (toilets, sinks, etc.) is composed of whole-grain industrial sand.

It is difficult for industrial sand producers to tightly control the chemistry of a deposit. Therefore, most consumers work closely with producers to develop a specification that can be acceptable to both parties. In general terms, the consumers of industrial sand are most concerned about consistency, which allows for more efficient furnace operation and consistent products.

Foundry Sand

In terms of volume, foundry sand consumers are the second highest consumers of industrial sand. The American Foundry Society (AFS) estimates that there are 2,950 foundries in all 50 states of the United States, and nearly 60% of them are in Illinois, Indiana, Michigan, Ohio, and Wisconsin. Foundry sand must generally exceed 98% SiO₂ in purity, and limits are placed on the amounts of CaO and MgO. Specifications for some foundries, however, can vary greatly, depending on price and availability. Much like glass

consumers, foundry consumers are most concerned about consistency of the sand.

The properties important for commercial foundry sand are grain shape, size distribution, base permeability, sintering point, clay content, and mineralogical composition (Dietert 1966). Foundries use industrial sand in the manufacture of molds and cores for casting metals such as steel, ductile iron, gray iron, and aluminum- and copper-based alloys (Wilborg and Henderson 1983). A casting is a metal part formed by pouring molten metal into a sand mold or metal die. The mold comprises two halves that, when mated, form a cavity into which the molten metal is poured (Whitlatch 1939). If an internal cavity is required in the casting, a core is placed inside the mold cavity. In molds, fine- to medium-grained sand is generally preferred, and coarser sands are preferred for cores.

Specialty sands such as chromite, olivine, fused silica, and zircon are increasingly displacing quartz sand in foundry applications. However, quartz-rich industrial sand still holds the predominant market share in foundry applications (Hoyt 1987) because of its abundance, which translates into cost savings for the end user. The use of specialty sand and industrial sand blends is increasing. Blends cost less than specialty sands and can create a superior mold by increasing permeability.

The effect of grain size on the permeability of foundry sand cannot be understated. After ramming, the permeability of the sand must remain high enough to allow gases to escape. Even a small amount of fine sand (– 0.106 mm) will greatly reduce the performance of foundry sand (Dietert 1966). The AFS grain fineness number is used in describing the results of a sieve analysis and is also a means of calculating the mean diameter of sand particles. The AFS grain fineness number is approximately the number of openings per inch corresponding to a sieve that would just pass a sand sample if its grains were of uniform size. It is approximately proportional to the surface area per unit weight of sand exclusive of any clay binder or matrix (Anon. 1978). To further characterize the size profile of a sand grain, the number of adjacent screens having 10% or more of the material retained on them can be noted (Hoyt 1987).

In addition to size, the shape of sand grains also affects the porosity of the mold (Zdunczyk and Linkous 1994). High porosity promotes high green strength and allows use of less binder in a mold. The more angular the sand grain, the lower the porosity and green strength of a mold. Angular grains also tend to resist compaction; therefore, the mold densities are 8% to 10% lower than for round grains (Zdunczyk and Linkous 1994).

Ground Silica

Ground silica (PV) is used as a functional filler and extender in many industrial applications, including paints and coatings, caulks, epoxy-based compounds, sealants, precision castings, and synthetic rubber. It is also the major batch component in the production of fiberglass. PV is an essential component of the glaze and body formulations of all types of ceramic products, including tableware, sanitary ware, and floor and wall tile. In the ceramic body, silica is the skeletal structure on which clays and flux components attach. The SiO₂ contribution is used to modify thermal expansion, regulate drying and shrinkage, and improve structural integrity and appearance. PV products are also used as the primary aggregate in both shape and monolithic-type refractories to provide high-temperature resistance to acidic attack in industrial furnaces.

The term PV contains two primary subsets of products: silica flour and ground silica. Silica flour generally is sold into lower value markets, and ground silica is generally sold into higher value markets. Table 3 presents typical chemical and physical specifications for PV products.

Surface-modified PV (chemically treated) and uncoated PV are conventionally used as a functional filler to modify the physical properties of a product (e.g., altering its thermal characteristics). In paint, PV is used in a range of products to increase durability, to improve weatherability, and as a pigment extender. Pigment extenders can provide significant value to consumers of PV, because a high-quality PV can reduce the need for high-priced pigments such as titanium dioxide (Guillet and Kriens 1984). Paint formulators select micron-sized products to improve the appearance and durability of architectural and industrial paint and coatings. High-purity silica contributes critical performance properties such as brightness and reflectance, color consistency, and oil absorption. In architectural paints, silica fillers improve tint retention, durability, and resistance to dirt, mildew, cracking, and weathering. Low oil absorption allows increased pigment loading for improved finish color. In marine and maintenance coatings, the durability of silica imparts abrasion and corrosion resistance. In plastics, PV provides dielectric properties and enhances the strength of the final product. PV is also valued for its stable chemistry, and it is used as an inert filler.

PV is also used in the production of chemicals. Silicon-based chemicals are the foundation of thousands of everyday applications, ranging from food processing to soap and dye production. PV is the main component in the production of sodium silicate, silicon tetrachloride, and silicon gels. These chemicals are used in household and industrial cleaners, to manufacture fiber-optic materials, and to remove impurities from cooking oil and brewed beverages.

Abrasives

Industrial sand enjoys significant market share as an abrasive. It is used to clean surfaces and is valued for its relatively low price, cutting capability, blasting profile, and availability. High-quality abrasive sand must be free of impurities such as carbonates or caliche, organics, and aluminum silicate minerals. Impurities greatly affect performance by reducing the cutting ability of the sand, creating a nonuniform blasting profile, or creating dust. Most consumers prefer angular sand.

Abrasive grades or sizes are indexed to application. Coarse grades are primarily used for large-scale blasting of iron or steel structures, and for removing thick coatings of unwanted material from a surface. Conversely, fine grades of sand are used for polishing surfaces and cleaning softer alloys such as brass and aluminum. Silica sand is also used in the apparel industry for "stone washing" denim products.

The abrasives market is highly competitive, and consumers are generally price conscious and often will compromise quality for price. In addition, health concerns regarding respirable silica have been a major factor in the abrasives market. Industrial sand also competes with many other abrasive products such as slag, garnet, fused alumina, and walnut shells, which do not contain crystalline silica. Although respirable dust can be mitigated by treating the surface of blasting-grade industrial sand with a chemical dust surfactant, producers can never fully mitigate the concerns surrounding respirable silica.

Proppant Sand

Known commonly as *proppant*, or *frac sand*, industrial sand is pumped down holes in deep well applications to "prop" open rock fissures and increase the flow rate of natural gas or oil. Proppant sands are generally added to the "pay zone" of an oil or gas well to increase the conductivity of the well. The conductivity of the well is the sum of the permeability of the proppant multiplied by the propped width of the fissure. Proppant sands are first categorized

Table 4. Proppant stress range

Proppant	Stress Range, psig
Class C sands	0–4,000
Class D sands	0–5,000
Class E sands	2,000–6,000
Surface modified sands (resin)	4,000–12,000
Ceramics	10,000–16,000

by the stress range that they can support (Table 4), and then by the mesh or sieve size. Mesh size is important to performance because sizing is a relative measure of strength. The smaller the porosity in proppants (smaller mesh sands), the more contact area available to support stress. Therefore, all larger mesh size sands exhibit less strength compared to smaller mesh size sands. The final method of categorizing proppant sand is the American Petroleum Institute's (API) specifications. The API testing procedure is known as RP-56.

The sand can be surface modified (resin coated) or nonmodified. The highest valued sands are clean, relatively dust-free, and round, and exhibit better permeability at higher well closure stresses. Under the same stress values, larger mesh sands are more permeable than smaller meshed sands. The hardness and overall structural integrity of silica sand combine to deliver the required crush resistance of the high pressures present in wells up to 2,450 m deep. Its relative chemical nonreactivity is required to resist chemical attack in the corrosive environments found downhole.

Nonmodified proppant markets primarily use two sands—"brown sand" and "white sand." Brown sand is primarily from the Hickory Sandstone of Texas and the eolian sand deposits of southern Colorado. The API recognizes the Hickory sand as a Class D sand and the Colorado sands as Class C sand. White sand is mostly produced from the St. Peter Sandstone near the Ottawa, Illinois, area, and is recognized by the API as Class E. In general terms, the brown sand is used in shallow well applications and the white sand is used in deep wells. The primary differences between the Class E and Class D sands are roundness, acid solubility, and crush strength. Class C sands contain feldspar, which significantly affects the performance of the material at depth. However, Class C sands can demonstrate superior performance compared to Class D and E sands in wells with lower closure levels. This is due to the angularity of the sand. Under higher stress loading (>4,000 psig), angular silica and feldspar particles crush and lodge in the pore throats of the sand pack; however, under low-stress environments, the Class C sands actually increase the permeability of the sand pack. Table 5 illustrates typical proppant grades. Each grade is used for a specific

Table 5. Typical proppant grades (sizes)

Metric, mm	U.S. Mesh Size
2.36 × 1.18	8 × 16
1.70 × 0.850	12 × 20
1.18 × 0.60	16 × 30
0.850 × 0.425	20 × 40
0.600 × 0.300	30 × 50
0.425 × 0.212	40 × 70

application. For each grade, 90% of the product should be within the size range specified.

Filtration Sand

Industrial sand is used in filtration of drinking water, processing of wastewater, and production of water from wells. Uniform grain shapes and grain size distributions produce efficient filtration bed operation to remove contaminants in both potable water and wastewater. Chemically inert, silica will not degrade or react when it comes in contact with acids, contaminants, volatile organics, or solvents. Silica gravel is used as packing material in deep-water wells to increase yield from the aquifer by expanding the permeable zone around the well screen and preventing the infiltration of fine particles from the formation.

The American Water Works Association (AWWA) and NSF International largely govern sand specifications used in filtration. No specifications strictly govern the shape of the sand grains; in general, both round and angular grains perform well. Round grains are valued for their flow characteristics, and angular grains are valued for their ability to trap solids. However, if the grains are too angular, they can lock and inhibit flow in a filter media. It is critical that the sand be uniform, be clean, and have a low effective size and a low uniformity coefficient. The effective size is the size of a sieve opening that will pass 10% by weight of a representative sample. For example, if the size distribution of a sand is such that 10% by weight is finer than 0.45 mm, the sand has an effective size of 0.45 mm (Anon. 1989). The uniformity coefficient of a filter sand is a ratio calculated by dividing the size of a sieve opening that will pass 60% of a representative sample of the sand by the size of a sieve opening that will pass 10% of the sample (the effective size) (Anon. 1989). In general terms, if the sand has a low uniformity coefficient, the sand will perform better as a filter media. Excess fines tend to retard flow, and excess coarse material does not offer sufficient filtering. Table 6 illustrates typical commercial filtration sand specifications.

Recreation and Building Materials

Industrial sand is used for golf course bunkers and greens and the construction of natural or synthetic athletic fields. Bunker sand is frequently blasted from greenside bunkers onto putting greens; therefore, an ideal bunker sand should contain less than 3% gravel (2 to 4 mm) and 7% coarse sand (0.25 to 1.0 mm). Further, an ideal bunker should contain 65% or more particles in the 0.25 to 1.0 mm range and 25% or less in the 0.05 to 0.25 mm range. Bunker sands should also be clean and contain low carbonates. Sands high in carbonates tend to exhibit crusting and setup. Crusting is the formation of a thin hard shell on the surface, and setup is the formation of a thick crust that extends as deep as water penetrates. Crusting and setup increase operating costs by requiring more maintenance to keep the bunker in a playable condition.

In golf and sports turf applications, industrial sand is the structural component of an inert, uncontaminated, growing media. Industrial sand is also used to repair greens and to facilitate everyday maintenance like roto aeration and fertilization. The natural

Table 6. Typical chemical composition and grain size of filtration sand*

* Acid solubility (1:1 HCl) 0.08%–0.11%. Specific gravity 2.64–2.66.

grain shape and controlled particle-size distribution of silica sand provide the required permeability and compaction properties for drainage, healthy plant growth, and stability. The United States Golf Association (USGA) typically controls the specifications for recreation sand grades used in golf bunkers and in green mixes. Typically, root-zone sand should contain no more than 3% particles ranging from 2 to 4 mm. Sands free of gravel are preferred. Sands containing more than 3% gravel are likely to damage mower blades and bed knives. An ideal root-zone sand should contain 60% or more particles in the 0.25 to 1.0 mm range, and no more than 10% of the particles in the 1.0 to 2.0 mm range, with an additional 5% or less in the 0.05 to 0.15 mm range.

Surface-modified industrial sand has also been recently introduced into recreation markets. The sand is coated with a dye to create a product that has many colors (blue, orange, black, red, purple, etc.). The colored sand is used primarily as play sand product.

Industrial sand is also the primary structural component in a wide variety of building and construction products. Because of its inert nature and wear strength, industrial sand has significant value in the building materials industry. Whole grain silica is used in flooring compounds, mortars, specialty cements, stucco, roofing shingles, skid-resistant surfaces, and asphalt mixtures to provide packing density and flexural strength without adversely affecting the chemical properties of the binding system. The building materials product lines of industrial sand producers have enjoyed significant growth during the 1990s, and demand continues to grow. Although industrial sand has significant competition from other industrial minerals (e.g., limestone), industrial sand tends to be more durable than competing materials, and thus more suitable for use in building materials applications.

GEOLOGY AND DISTRIBUTION OF MAJOR DEPOSIT TYPES IN THE UNITED STATES AND CANADA

The industrial sand deposits mined in the United States vary greatly in chemistry, location, and physical characteristics. In general terms, the highest quality industrial sand deposits are located in the Midwest. The deposits usually contain less than 20% deleterious materials (Pettijohn, Potter, and Siever 1987), and are contained within the mid-continent marine quartz arenites. Table 7

shows typical chemistry of a high-quality midcontinent sand, from the St. Peter Sandstone.

Industrial sand deposits in the western and southwestern United States are generally of lower quality than the industrial sands produced in the Midwest. The western and southwestern deposits have not undergone as many cycles of erosion and weathering; therefore, these sands tend to be less rounded and contain more deleterious material. In some cases, feldspar content exceeds 25%. Table 8 depicts the chemistry of a typical Pacific Coast sand, from the Santiago Formation.

Industrial sand deposits in the continental United States occur in five geologic provinces (Heinrich 1981): Pacific Coast, Rocky Mountain Cordillera, Midcontinent, Coastal Plain, and Appalachian Belt (Figure 1). Each province yields industrial sand products that are unique and directly related to the local geologic conditions. The geologic history of the deposit directly influences its size distribution, grain shape, and chemistry. The separable parameters then directly influence the markets and commercial value of the deposit.

Pacific Coast

Production from California dominates the Pacific Coast province. Minor industrial sand deposits are used for local markets in Oregon

Adapted from Adapted from Zdunczyk and Linkous 1994.

Figure 1. Geologic provinces of industrial sand deposits in the United States

and Washington; the majority of commercial production, however, comes from California. Pacific Coast province production is primarily from immature, feldspathic, clayey sands of Pliocene to Pleistocene/Pleistocene age. Commercial production also takes place in central California where hydraulic gold tailings are reprocessed to yield industrial-grade and filtration products.

Santiago Formation

Sand is extracted from the Eocene Santiago Formation in Orange County, California, and sold into the industrial/building materials markets. The medium-grained sandstone consists of approximately 70% quartz, and the remainder of nearly equal percentages of clay and feldspar (Silva 1985). Table 8 shows the typical chemistry of Santiago Formation industrial sand. The sand crops out for several miles to the north and south of the developed deposit near San Juan Capistrano. The formation contains evidence of several local sea-level transgressions on the basis of sand gradation and the presence of unpredictable clay/shale banding. Three mappable members of the Santiago Formation are recognized: the lower, middle, and upper members represent an overall transgressive sequence of non-marine to estuarine to shallow marine sandstone, siltstone, and mudstone. The deposit is more than 400 m thick, and faulting of regional and local nature is common. The deposit has a gradational contact with the underlying Silverado Formation, the source deposit of past industrial sand production near Corona.

Saugus Formation

Five miles north of Santa Susana in Ventura County, California, sand is extracted from the Pleistocene Saugus Formation and sold into industrial/building material markets. The formation is typical of deltaic deposits, consisting of conglomerate, sandstone, and siltstone. The mining area is in the Soledad Basin, a depression that was cut off from the sea until subsidence during the Miocene allowed marine transgression into its western extension. The Saugus Formation represents the resumption of fresh water deposition after the sea regressed at the end of the Pliocene (Norris and Webb 1990).

Recent Beach Deposits

Beach sands have been commercially developed in Monterey County, California. The sand is harvested using dredges and sold into filtration and industrial/building materials markets. The sands are of Holocene age and are regenerated annually by storm events.

The sand is coarse grained and characterized by high feldspar content and iron staining.

Fluvial Sands and Gravel

In the Marysville and Yuba City area of north-central California, hydraulic mining tails are reprocessed to produce filtration and industrial/building materials products. The deposits are the result of historical hydraulic gold mining in which vast quantities of quartzose Tertiary sand and gravel flowed into streams draining into the Yuba and American rivers. They are typically high in feldspar and other accessory minerals. The sands are a low-grade product; because of the location and market demands, however, they have a high commercial value.

Ione Formation

Sand is extracted from the Eocene Ione Formation in Amador County, California. The sand is mined from a site south of the town of Ione and is used in glass production. The deposit is composed of quartz sand and clay in an approximately 60-40 mix (Silva 1985). The Ione Formation is locally exposed from Oroville in Butte County to the north to Knights Ferry in Stanislaus County to the south. The source of the Ione sediments was deeply weathered granitic and metamorphic rocks of the ancestral Sierra Nevada that were uplifted in the Late Jurassic during the Nevadan Orogeny. The sediments were deposited in lagoons and shallow basins along a broad, swampy coastal plain bordering the Eocene sea. The sediments were altered by chemical weathering, covered by volcanic material in the Miocene and Pliocene (Anon. 1956; Zdunczyk and Linkous 1994), and eventually exposed by renewed uplift and erosion.

Oro Grande Quartzite

Western San Bernardino County has been the principal source of manufactured industrial sands for Southern California. The deposits are located east of the town of Oro Grande and north of Victorville. Massively bedded quartzite (thought to be of the Carboniferous) Oro Grande and Hodge Series occur in extensive bodies as much as 100 m thick (Silva 1985) with typical silica content of 98% to 99%. Although the quartzite is relatively pure, it has not been used extensively in industrial markets. The material is used primarily in the ceramic and filler markets.

Puget Group Sands

A commercial deposit of industrial sand in King County, Washington, is mined for feldspathic sand used in the local glass and recreation markets. The sands are derived from glacial outwash sediments from the last ice age—part of the Fraser Glaciation. The sands are not high quality and are used in local markets because of freight advantages.

Rocky Mountain Cordillera

The Rocky Mountain Cordillera is not a major source of industrial sand production. Commercial deposits exist in Colorado, Idaho, Nevada, and eastern Washington. The commercial Colorado deposits are Quaternary dune deposits. The Idaho deposit is a lacustrine Pliocene-Pleistocene deposit. The Nevada deposits are tectonically crushed quartzite and reworked sandstone. Washington industrial sand is a manufactured industrial sand from weathered quartzite.

Quaternary Eolian Dunes

The Colorado Piedmont offers some opportunities for industrial sand exploration and production. The Colorado Piedmont is a broad erosional trench that separates the southern Rocky Mountains from

the High Plains. Structurally, the site lies along the western flank of the Denver Basin. Relatively flat uplands and broad valleys characterize the present-day topography of the Colorado Piedmont in this region. In El Paso County, Colorado, Quaternary eolian dunes and other surficial deposits are mined for proppant, filtration, industrial, and recreation sands. The eolian sand deposits are coarse to medium sand derived mainly from stream alluvium and distributed east of the source area by wind. The source rock appears to be the Pikes Peak Granite. The sand is subrounded to subangular, frosted, and contains approximately 90% to 95% quartz and 5% to 10% feldspar. The eolian dunes range in thickness from 1 to 10 m. Other surficial deposits have been commercially viable and are considered to be typical eolian and fluvial transported sands and gravels. These deposits also range in thickness from 1 to 10 m.

Idaho Group

The Emmett feldspathic sand operation is located in and near the town of Emmett in Gem County, Idaho. The deposit is mined for a wide range of products, which are sold into the glass, foundry, building materials, and golf course industries. The feldspathic sand is marketed on the basis of product chemistry and physical specifications (W.A. Bratney, personal communication).

Within the structural graben represented by the Late Miocene to Early Pliocene rift that developed along the present-day course of the Snake River, volcanic eruptive events associated with the Columbia River basalts blocked the natural stream drainages. Historical Lake Idaho developed as a freshwater lake into which Pliocene-Pleistocene sediments were deposited. Sedimentation is interpreted to have occurred in many lakes interconnected at times by a river system that was present in the newly formed rift environment. This assemblage, collectively known as the Idaho Group, is divided into a number of recognized formations, including, from oldest to youngest, the Poison Creek, Banbury Basalt, Chalk Hills, and Glenns Ferry formations. Many of the Idaho Group sediments are covered by basalt flows and sediments deposited in recent times. Coarse-grained sand and gravel detritus from the tonalites and quartz diorites of the Idaho Batholith eroded rapidly into Lake Idaho during a period of active regional uplift and formed a coarse fluvio-deltaic wedge in the finer grained lacustrine deposits near the top of the Idaho Group. Mining takes place at or near the contact of the Chalk Hills with the overlying Glenns Ferry Formation. The stratigraphic section here is approximately 30 m thick (W.A. Bratney, personal communication). Mine exposures exhibit prominent cross-bedding, scour channels, and extreme variability in sediment size. The mine has fine clay horizons at the top and bottom of the developed zone. Mining is accomplished with a front-end wheel loader that fills over-the-road trucks.

The ore horizon consists of quartz clasts present in amounts up to 80% (W.A. Bratney, personal communication). Feldspars are the principal accessory minerals. Microcline occurs in amounts ranging from 16% to 19% by weight. Oligoclase is very abundant and can range between 45% and 55% by weight (W.A. Bratney, personal communication). Muscovite and, to a lesser extent, biotite are abundant in the finer grained lenses frequently observed in the deposit. The micaceous minerals have not been quantified, but they are estimated at less than 5% of the mineral assemblage. Trace amounts of magnetite, ilmenite, rutile, and garnet also occur.

Baseline Formation

The Cretaceous Baseline Formation is mined for glass, foundry, industrial, ceramic, and filler applications near Overtown, Clark County, Nevada. The Baseline Formation is relatively limited in outcrop and currently hosts only one commercial operation. The

Baseline is interpreted to be reworked Jurassic age Aztec Sandstone. It is white to buff and is weakly cemented by clay, calcium carbonate, and minor to moderate iron oxide. The sand is mined by scrapers, washed in the open pit, and slurried to a screening plant at Overton. Unprocessed sand contains approximately 97% SiO₂, and washed product contains approximately 99% SiO₂ (S. Castor, personal communication).

Eureka Quartzite

The Eureka Quartzite is mined near Mercury, Nevada. The deposit produces limited quantities of industrial- and recreation-grade manufactured sands for local and regional markets. It consists of a limited east-west zone of intensely fractured quartzite. The deposit is unique in that it has undergone intense cataclastic brecciation, most likely caused by local and regional faulting. The deposit is estimated to be more than 50 m thick; it is overlain, however, by thick limestone/dolomite overburden. The Eureka Quartzite is widespread throughout Utah and Nevada, but most deposits are not close enough to transportation or markets to be commercially viable.

Addy Quartzite

The Addy Quartzite, mined in Stevens County, Washington, for use in the glass industry, varies from unconsolidated sand to competent quartzite. The deposit has been described as tabular in nature, 60 to 90 m thick, and 5 km long (Zdunczyk and Linkous 1994). Where mined, the material has been leached to a highly friable condition. It is buff to white (Reed 1974), and grain shapes vary from angular to subangular.

Midcontinent

Zdunczyk and Linkous (1994) described the industrial sand resources of the Midcontinent Area in detail, and the distribution of deposits in this area has changed little since that publication, from which the following text borrows heavily.

These Midwest sands are mature to supermature, multicycle sheet sands that are Early Paleozoic in age, flat lying, and moderately consolidated. The quality of the deposits has been greatly enhanced by multiple cycles of erosion, winnowing, and redeposition.

St. Peter Sandstone

The Ordovician St. Peter Sandstone is the type deposit for multi-use, high-quality industrial sands. The formation is uniform, widespread, quartz arenite sheet sand. It is exposed in southeastern Minnesota and crops out across the southern margin of the Wisconsin Dome into eastern Iowa. Exposures extend south into Illinois, and across the flanks of the Ozark Dome in eastern Missouri and northern Arkansas (Bates 1960). The St. Peter has also been discovered in the subsurface in South Dakota, where it joins with basal clastics of the Winnipeg Formation (Bunker et al. 1989).

The St. Peter is generally interpreted as having a marine origin. It is a multicycled sand whose source is inferred to have been Precambrian quartzites of the Canadian Shield and Cambrian and Early Ordovician sandstones (Lamar 1927). Studies have shown the St. Peter to be a transgressive sheet sand of reworked beach deposits formed along the edge of a northwestward advancing sea (Bates 1960). The St. Peter is valued for its well-rounded, homogeneous, and inclusion-free sand grains. Sand chemistry usually exceeds 97% silica, with minor amounts of clay and feldspar (Harben and Bates 1990). Table 7 gives the typical chemistry of processed St. Peter Sandstone. The material is white to buff and is typically referred to in the industry as white sand.

In the Ottawa District of Illinois, the best known commercial mining area for St. Peter Sandstone, the formation was deposited on

an erosional surface of underlying Shakopee Dolomite and is up to 130 m thick (Bates 1960). Postdepositional erosion has reduced the deposit to approximately 70 m thick. Most production occurs in the upper portion of the deposit because the deposit typically becomes finer with depth, and feldspar, clay, and iron also increase. Because of the nature of the deposit, mining costs are low and recovery is high. Although the St. Peter Sandstone is, arguably, the most valued industrial sand on the market, the selling prices are some of the lowest on the market. This is due to its wide distribution and market saturation. More than six major operations exist within a 60-km radius, and a large volume of high-quality sand is available. Because of low production costs, Ottawa District sands can be economically transported to western United States for glass, filtration, proppant, and industrial markets.

Hickory Sandstone

The Hickory Sandstone member of the Cambrian Riley Formation is mined near Brady, Texas. The Hickory is as much as 167 m thick (Cornish 1975), but mining thicknesses generally average 30 to 40 m. The Hickory yields products used in the proppant, filtration, and foundry markets. It is often referred to in the industry as a brown sand. The Hickory outcrops along northeast-trending fault blocks of the Llano uplift area of central Texas and dips away from the uplift in all directions. It lies unconformably on the irregular surface of the Precambrian Texas craton. The contrasting and variable thickening and thinning of the Hickory suggest topographic control during deposition.

The Hickory is one of many lower Paleozoic cratonic sandstones of North America. The depositional environment was largely transgressive. The Hickory can be divided into the lower, middle, and upper facies (Pettigrew 1988). The lower facies is a fine- to coarse-grained, poorly sorted sand with rounded to subrounded grains and minor to moderate amounts of siltstone and shale. The lower facies can be most easily recognized by the planar and festoon crossbeds with large-scale foresets (Cornish 1975). It contains minor to moderate amounts of feldspar. The middle facies interfingers with the lower facies and is composed of layers of coarse- to medium-grained sand interbedded with fine-grained sand, silt, and shale. The middle Hickory can be most easily identified by the massive bedding of the coarse sand zones, and the planar to wavy laminations in the fine-grained zones. The upper facies is medium to coarse grained, well rounded, and hematitic (Cornish 1975). The upper facies has not been commercially mined. To date, all commercial activities take place in the lower and middle facies.

Black Hand Sandstone

The Mississippian-age Black Hand Sandstone Member of the Cuyahoga Formation is up to 60 m thick and consists almost entirely of nonmarine, cross-bedded, coarse-grained, conglomeratic sandstone (Kammer 2002). The Black Hand has been interpreted as braided river sediments filling incised-valleys within finer-grained marine sediments of the Cuyahoga. The Black Hand has been mined for more than 100 years as a source of glass sand, PV, and recreational sand for local and regional markets of the Knox County, Ohio, area. The sands vary from buff to dark brown, and subangular to angular.

Massillon Sandstone

The Massillon Sandstone Member of the Pennsylvanian-age Pottsville Formation has been a source for glass and recreation sand for more than 100 years. The commercial deposit in Perry County, Ohio, produces industrial sand for local and regional markets. The sand is white to buff, medium to coarse grained, and subangular to

angular. The deposit averages approximately 15 m thick, with upper and lower 1-m borders containing moderate to high amounts of iron oxide or iron sulfide or both.

Sylvania Formation

The Sylvania Formation is found in southern Michigan and northern Ohio. It is recognized as a high-quality glass sand. The sand was interpreted by Bates (1960) as a basal-blanket quartz arenite of Middle Devonian age, and is the lowermost unit of the Detroit River Group. The deposit, which dips gently to the northwest, has been structurally influenced by the Michigan Basin and by the Findlay Arch in Ohio, where the Sylvania rests on the northwestern flank. Heinrich (1977) suggested that the source for the Sylvania is the St. Peter Formation, which outcrops to the north. The Sylvania is believed to be a littoral eolian sand that was deposited in a near-shore environment. It is friable, pure, and often weakly cemented by carbonates. The sand is fairly well sorted; significant variations, however, can occur along strike. The larger grains of the deposit are well rounded; small size fractions can be angular, however, because of secondary silica overgrowths, which make the rock resistant to weathering (Heinrich 1977).

Oil Creek and McLish Formations

The Oil Creek and McLish formations of southwestern Oklahoma yield high-quality glass, ceramic, and PV-grade sand. The deposits are generally poorly consolidated and contain minor amounts of clay. The grains tend to be well rounded and frosted, and the gradation trends toward a fine sand. Because of the relatively fine-grained nature of the deposits, they tend to have more value in PV applications than as a glass sand. The deposits are part of the Ordovician Simpson Group, which consists of 300 to 700 m of sandstone and limestone with interbedded green shales (Buttram 1913). The Oil Creek and McLish formations within this group have been considered lithologically equivalent to, and of the same age as, the St. Peter Sandstone (Ham 1945).

Jordan Sandstone

The Jordan Sandstone consists of three distinct members: (1) the Norwalk Member, a fine-grained, silty, yellow quartzose sandstone; (2) the Van Osse Member, a coarse- to medium-grained, white or yellow orthoquartzite that is mined for proppant and foundry sands; and (3) the Sunset Point Member, a dolomitic and argillaceous quartz sandstone containing pebble-size clasts of dolomitic sandstone (Ojakangas and Matsch 1982). During the Late Cambrian, most of the central Midcontinent Area was covered by an epicontinental sea characterized by carbonate deposition. The regression of this sea was followed by the prograding of sandstone units eroding from the Wisconsin Dome across much of present-day Minnesota, Iowa, and northeastern Missouri. These Upper Cambrian sandstone units included the Lower Jordan Sandstone in Minnesota (Bunker et al. 1989; Zdunczyk and Linkous 1994). The Jordan is primarily mined in Minnesota for proppant and foundry applications.

Appalachian Belt

Zdunczyk and Linkous (1994) described the Appalachian Belt area in detail. The distribution of deposits there has changed little since 1994. Therefore, this section borrows heavily from their work. The area produces some high-quality industrial sands for regional markets. Although the sands are more than adequate for regional markets, they lack the preferred physical and chemical characteristics of the Midwest sands. The sands were deposited in thick wedges of nonmarine clastic sediments during the Taconic Orogeny in Late Ordovician time. As erosional unloading occurred following

large-scale tectonic events, terrigenous material shed from the fold-thrust mountain belt was deposited westward into an adjacent foreland basin. Following the orogenic events—the Silurian and Early Devonian—were periods of relative quiescence. When erosion and subsidence slowed, the siliclastic sediments that accumulated in the foreland basin were reworked into high quartz sandstones (Smosna 1992).

Clinch Formation

The Clinch Formation is mined near Rogersville, Tennessee, for glass, PV, recreation, and building materials. The sand grains are subrounded to subangular. The geologic history of the deposit is complex and includes alluvial fan, coastal plain, and tidal river environments, and near-shore shelf sand wave complexes (De Witt and Milici 1989). The Clinch is interpreted to be the stratigraphic equivalent of the Tuscarora Formation to the north.

Oriskany Group

The Lower Devonian Oriskany is actually the Ridgeley Member of the Old Port Formation. The deposit, however, has typically been referred to as the Oriskany. The Oriskany has been a significant source of high-quality industrial sands used in glass, foundry, PV, and building materials markets. The commercial portion of the Oriskany is a hard, white to bluish-gray, clean marine quartz arenite that extends from New York into Virginia. Current mining is limited to a folded belt of the Central Appalachians in the Virginia, West Virginia, and Pennsylvania tristate area. In this area, the Oriskany is well sorted and averages 90 m thick. Fracturing and jointing have allowed groundwater to leach out the calcareous matrix, resulting in a friable to loose sandstone (Harben and Bates 1990). South of New York, the source of the Oriskany sand was most likely the Silurian and Cambrian quartzites in southeastern Pennsylvania (Berkheiser 1985). The predominance of marine fossils and conglomerate lenses suggests that it was deposited under tectonically stable, near-shore, shallow water conditions (Bates 1960).

Coastal Plain

Along the Atlantic coastal plain, unconsolidated, nearly horizontal sediments of Late Cretaceous to Holocene age are mined for many industrial applications. The distribution of deposits in the Coastal Plain Area has changed little since 1994. This section borrows heavily from Zdunczyk and Linkous (1994).

Cohansey Formation

In the coastal plain of southern New Jersey, sand of the Miocene Cohansey Formation is mined for use in glass, ceramics, PV, foundry, filtration, building materials, and recreation markets. The formation consists of a 30- to 70-m-thick section of poorly sorted, subangular, fine- to medium-grained sand containing minor clay (Zdunczyk and Linkous 1994). Tertiary sediments that make up the New Jersey Coastal Plain are inferred to have been deposited in an environment that ranged from continental to midshelf or outer-shelf marine. The sources of these sediments appear to be the Piedmont Lowland, Valley, and Ridge; the New Jersey highlands provinces; and Cretaceous and Tertiary beach sands. The sediments were carried and deposited on a submerged coastal shelf by southeastward-flowing streams and were then reworked and upgraded by marine action (Wolfe 1977).

Pinehurst Formation

The Late Miocene to Early Pliocene Pinehurst Formation of central South Carolina and south-central North Carolina is a valuable source of high-quality industrial sand. The Pinehurst ranges from a

thin veneer to more than 10 m thick and contains angular to subrounded sand that is generally poorly sorted and medium to very coarse in grain size (Zdunczyk and Linkous 1994). The sand varies from nearly white to yellow-orange and averages about 90% quartz. The Pinehurst is inferred to be of eolian origin based on the presence of well-defined dune topography, in verse grading in some cross beds, and the lack of clay, silt, or fossils (Nyström, Wiloughby, and Price 1991).

McNairy Sand

The McNairy Sand is a source of industrial sand in western Tennessee. The McNairy is part of the Gulf Coastal Plain—Upper Mississippi Embayment. The McNairy was considered by Russell and Parks (1975) to have been deposited in a cyclic, near-shore geologic environment. The outcrop belt parallels the Tennessee River and varies from approximately 19 km wide in McNairy County to approximately 13 km wide in Benton County. Zdunczyk and Linkous (1994) describe the McNairy section as (1) a regressive, near-shore basal sand that is fine grained and contains heavy minerals; (2) a middle wedge of coarser-grained sand that appears to be fluvial, deltaic, and partly estuarine in origin; and (3) an upper transgressive marine sand, which is present only in southwestern McNairy County.

Florida

Industrial sands are produced throughout Florida for local and regional markets. Glass-grade sand is produced near Davenport, Plant, and Edgar. Zdunczyk and Linkous (1994) described the Citronelle Formation as a fluvial blanket deposit of highly cross-bedded sand, clays, and gravel extending across western Florida, Alabama, and Mississippi. It attains a maximum thickness of approximately 50 m in western Alabama. It is inferred that the Citronelle sediments were deposited as coalescing deltas by several rivers that emptied into the Gulf of Mexico (MacNeil 1950). Closely associated with the Citronelle Formation are the Pleistocene marine terraces near Davenport, Plant City, and Edgar (Olson 1970). Four marine shorelines have been recognized in the Gulf Coast terraces, representing the inland limits of transgressive seas. These marine terraces consist of fine- to medium-grained, well-sorted, unconsolidated sand. The quartz grains are generally clear to milky, and iron staining and organic materials are not uncommon (Cathcart 1963).

Canada

Industrial sand production takes place across Canada. The provinces of Quebec, Ontario, and Alberta are the primary producers of industrial sand, followed by Saskatchewan, British Columbia, and Nova Scotia (Dumont 2001).

In Newfoundland and Labrador, the Roy's Knob quartzite deposit is mined for use in silicon metal. New Brunswick has two active operations where material is mined and processed for use in blasting, foundry, filtration, recreation, and flux markets. Quebec has several active operations where quartzite is mined near Saint-Donat-de-Montcalm, north of La Mabaie, and from sandstone deposits at Saint-Canut, Sainte-Clotilde-de-Chateauguay, and Saint-Remi-d'Amherst. Unconsolidated deposits are mined for mixed uses at Saint-Joseph-du-Lac, Ormstown, and Saint-Bruno-de-Guigues. Ontario has the largest production with sources at Badgley Island, Elgin Quarry, Fripp Quarry, and the Ellis Quarry. Industrial sand is produced in Saskatchewan in the Amisk Lake area, northeast of the village of Hudson Bay, and Prince Albert. Sand dunes are mined in Alberta in the Bruderheim Area. Industrial sand is also produced in Peace River. In the Golden Area of British Columbia, industrial sand is mined for varied industrial applications.

Mt. Wilson Formation

In the Rocky Mountains near Golden, British Columbia, a zone of friable quartzite within the Ordovician Mt. Wilson Formation is mined for mixed industrial uses. The rock is fine grained, white, and massive (Zdunczyk and Linkous 1994). The quartz grains are well rounded and average 0.25 to 1 mm in diameter. The friable zone that is mined lies along the crest of an anticline at the northwestern exposure of the formation (Zdunczyk and Linkous 1994).

Potsdam Formation

Near St. Canut, Quebec, the Cambrian Potsdam Formation is mined for high-purity industrial sand. In southeastern Ontario, the Potsdam is the lowermost Paleozoic formation present, and it is assumed to be the stratigraphic equivalent to the Potsdam in New York (Keith 1949). Both deep-water and near-shore facies have been identified. The near-shore facies appear to contain the purest sandstone (Guillet and Kriens 1984).

The Potsdam can vary from white to red, depending on whether the matrix is primarily ferruginous, calcareous, or siliceous (Zdunczyk and Linkous 1994). Where mined, the material is a white, massive, saccharoidal sandstone with a siliceous cement (Keith 1949). When crushed, the sandstone easily breaks into angular to subrounded grains, more than 80% of which are between 0.60 and 0.15 mm.

Bar River Formation

On Badgley Island, the Precambrian Bar River Formation is mined for varied industrial applications. According to Guillet and Kriens (1984), the Bar River is the youngest and purest of a series of three quartzite units at the top of the Cobalt Group in the Huronian Supergroup of middle to late Precambrian age. The Bar River is typically light gray to white (Zdunczyk and Linkous 1994). Where completely recrystallized by metamorphism, it consists of interlocking grains of quartz, which caused the rock to be extremely hard and to break across grains with a conchoidal fracture (Hewitt 1963). Where metamorphism was less intense, it is easier to see that the Bar River was originally made up of intergradational units of well-sorted and -rounded, fine- to medium-size sand grains (Guillet and Kriens 1984).

GEOLOGY AND DISTRIBUTION OF MAJOR DEPOSITS OUTSIDE NORTH AMERICA

Little has been published on deposits of industrial sand outside North America. Harben and Bates (1990) briefly described some European deposits, and information is available on some Australian deposits. Industrial sand deposits in China and India, however, which may become important in the near future, are not described in the literature.

Europe

The industrial sand deposits mined in Europe vary greatly in chemistry, location, and physical characteristics. The primary markets are glass, foundry, and building materials. The author could not find information in English-language literature on deposits in many of the important producing countries in Europe, such as Germany, Austria, France, and Spain.

Industrial sand is produced in the Mol, Maasmechelen, and Charleroi districts of Belgium, and in the "silversand" area near Heerlen, the Netherlands (Harben and Bates 1990). According to Harben and Bates (1990), the deposits are Pliocene sands that are valued for their low iron content (less than 0.01% Fe₂O₃). The high-grade, low-iron sands are used in the production of crystal glass, and the lower-quality sands are used in the production of

sheet glass, ceramics, silica flour, and silica carbide, and in building materials. The combined production of Belgium and the Netherlands is estimated to be greater than 20 Mtpy.

Scandinavia and Portugal produce high-quality industrial sands as a by-product of feldspar production from quartz-rich pegmatites. The silica sands produced from these sources contain 99.6% to 99.75% SiO₂, 0.03% to 0.06% Al₂O₃, and 0.2% to 0.5% Fe₂O₃ (Harben and Bates 1990).

In the United Kingdom, industrial sand deposits range in age from Carboniferous to Recent (Harben and Bates 1990). More than 50% of the production comes from Pleistocene to Holocene deposits of fluvioglacial, in terstadial, and eolian origin. Cheshire and Lancashire are important areas of production for glass, ceramics, and foundry sands. Approximately one third of the production is derived from Cretaceous beds south of London.

Australia

Australia produces industrial sands for local and regional markets. The primary markets are in glass and foundry applications. In the New South Wales area, container glass deposits are concentrated near the "inner barrier" dune deposits on the Tilligerry Peninsula near Tanilba Bay. The primary source for high-iron sand used in amber glass is the Salt Ash mine at Williamstown and a deposit at Londonerry, near Penrith. The New South Wales area is also a major producer of foundry sand from the "outer barrier" dunes of Stockton Bight.

In South Australia, industrial sand for foundry markets is mined from Holocene dunes near Sandy Creek, Tailem Bend, and Balaklava. Other significant industrial sand sources are the Glenshera sand pit near Mount Compass, 50 km south of Adelaide (Pain, Shaw, and Valentine 1999), and the 23-Mile lump silica deposit near Whyalla.

The Glenshera deposit contains Permian fluvioglacial sand, and portions of the deposit were reworked during the Tertiary. Up to 10 m of high-iron sand overlies approximately 80 m of low-iron sand. The low-iron sand is processed for container glass markets, and the high-iron sand is processed for amber glass and foundry markets (Valentine 1989).

Industrial sand is mined at the 23-Mile deposit for use as an additive in blast furnaces (Valentine 1989). The deposit was described by Valentine (1989) as a north-south trending quartz reef. The deposit is approximately 8 km long within dark gray volcanoclastic grit and sandstone of the Proterozoic Moonabie Formation.

TECHNOLOGY

Exploration

Like most industrial minerals, exploration for industrial sand begins with transportation and marketing studies. Understanding the location of competitors and distance to markets allows a potential producer to determine if a project warrants further investigation. For example, many potential high-grade manufactured sand sources exist in Idaho, Utah, and Nevada; the deposits have never been commercially viable, however, because of their distance from markets. Nonetheless, the complexification of industrial sand exploration has been changing in the last 10 years. Most deposits are well known, but the increase in demand in the western United States and emigration of population to that area have created a shift in industrial sand exploration. Consumers are now willing to consider local, more cost-effective sources of industrial sand rather than pay high freight premiums. This is particularly true in the building materials and recreation markets.

Although conventional exploration methods still apply, progressive industrial sand suppliers must now consider whether or not

a deposit can be permitted before investing significant capital into an exploration program. Planning, land use, zoning, and general regulatory requirements are as important as the chemical and physical properties for any potential deposit. Industrial sand exploration has become increasingly computerized, and computer processing allows rapid integration with marketing and regulatory concerns. With the advent of affordable geographic information software (GIS) and global positioning system (GPS) technology, industrial sand suppliers can quickly and efficiently review and catalog deposits. Transportation networks can be easily integrated into the model, and the company can quickly determine haul rates and commercial viability. Likewise, where available, county zoning maps and wildlife habitat, floodplain, wetland, and population density overlays can be placed on the model to determine if the deposit can be permitted.

Exploration targets can cover entire physiographic regions or can be limited to a certain "haul distance" from a given consumer. After determining what markets the supplier desires to serve, the supplier then begins the process of exploration. This will involve detailed literature searches. Many states and counties have readily available information that will assist the potential producer in determining if a location warrants further review. Once a site is identified, the company should conduct a detailed regulatory and land status review to determine if the deposit can be permitted within the allotted time and at a reasonable cost. Once the company determines that the deposit can be permitted, physical evaluation can be initiated.

Depending on location, exploration permitting can be a lengthy process. If the deposit is located on public land, community involvement and participation will take place. It is in the best interest of the company to develop relationships with all stakeholders and conduct business in a transparent and responsible manner. In the current regulatory environment, it is critical to develop relationships with all stakeholders: neighbors, elected officials, regulators, and environmental groups. Although additional costs and delays may occur because of the relationship-building phase of the exploration project, the company will quickly learn if the public will "allow" a site to be permitted.

During exploration, it is important to collect clean, unoxidized samples. The type of laboratory analysis that is required is contingent on the projected markets to be served. Roundness, gradation, chemistry, and sphericity must be analyzed for proppant, foundry, and filtration markets, whereas a stucco consumer may be concerned with only gradation and iron content. Furthermore, end market considerations vary by region. Colorado stucco sand consumers prefer round sand and California stucco consumers prefer angular sand. It is important that the company fully understand aesthetic and chemical requirements for their prospective markets.

As population centers continue to shift, deposits that have had no commercial value are garnering the attention of major producers. Several small start-up operators tried to develop deposits in the 1990s, but most were unsuccessful. This trend appeared related to the drop in gold prices in the 1990s and subsequent migration of small gold exploration companies into industrial minerals, and a rapid increase in the industrial sand demand in California. Most startups are unsuccessful; this generally is related to the complexities of the market and a general lack of understanding of freight costs.

Economic industrial sand deposits are market driven; therefore, deposits are developed in a wide variety of geologic regions. Physical exploration techniques are varied and depend on the site conditions. In unconsolidated deposits where the water table is high (Gulf Coast deposits), a rotary drill rig with a split-spoon sampler

or a vibrocore rig is recommended. In this type of exploration, contamination from the sides of the hole is common. If contamination is a concern, care must be taken to stabilize the walls of the hole. Bentonite-based drilling mud can be used, but clay-based mud can lead to erroneous chemical results and inflated clay matrix values.

Auger and suction drilling can also be used in unconsolidated deposits. Auger and suction drilling is recommended only in unconsolidated deposits where the water table is not a concern. Auger and suction drilling should be used only where contamination (sloughing and mixing) is not a major concern. When using an auger, the flights are either driven into the deposit by hand or rotated mechanically. In suction drilling, a polyvinyl chloride (PVC) pipe is driven into the deposit and connected to a suction device. Both methods will yield quick and inexpensive results; the sample integrity, however, is not as good as split-spoon sampling.

In consolidated deposits, reverse circulation can be used for quick and inexpensive (compared to core) results. Reverse circulation drilling, though, may mix samples and is likely to add clay from the drilling fluid to the sample matrix. Reverse circulation is an excellent tool when used with core drilling.

Core drilling yields the best data for geologic modeling. A drill rig equipped with NX size (54.9-mm diameter) wireline coring capability is generally adequate to obtain samples. If the rock is fractured or friable, the geologist should consider using a larger diameter core.

Percussion drilling can also be used. Percussion drilling is not a preferred method but can yield meaningful data if the deposit is well understood. The cuttings generated by percussion rigs are valuable as a “quick and dirty” assessment or for infilling data holes. Percussion drilling should not be used as an exclusive exploration tool.

If the deposit permits, trenching can also be a valuable tool. However, care must be given to sampling methods and the safety of the sampling team. Trenches can yield invaluable information and should not be discounted as a tool when conditions permit.

Once samples are collected, it is imperative that the field geologist work closely with the production team to ensure that the samples are thoroughly described and prepared for analysis. The geologist should include the type of iron minerals present and severity of iron staining in sample descriptions. Matrix material and cement, refractory minerals, and mineral inclusions within the quartz are also important characteristics to note. Grain size, particle distribution, and grain shape are also market-critical concerns that the geologist must consider.

Once all of the data are collected, reserve estimates must be calculated. There are many definitions for reporting reserves, but if the company is publicly traded, they must comply with the Security and Exchange Commission's (SEC's) industry guide (SEC 2005). If the company is not publicly traded, then the company can use their discretion as to how to report reserves. Nonetheless, an industry-recognized standard should be selected such that the results of the modeling are credible. Computerized reserve calculation models are an invaluable tool, and most operators now use computer-assisted modeling. Most geology departments are understaffed, and computer modeling allows a company to develop a quick and accurate model. The model is only as accurate as the data; therefore, the use of models must be based on a reasonable understanding of the geology and proper laboratory procedures.

Laboratory Testing

The type of laboratory testing required is directly related to the market served. In general terms, all deposits should be analyzed for a full suite of oxides and elements. Samples should also be washed,

dried, and sieved. If the proposed market is proppant sand, then acid solubility, crush strength, and conductivity tests must occur. If the filtration market is being considered, then leach tests must be performed to ensure that the material will not exceed drinking water standards. In general terms, a company should consider conducting as many tests as possible. Many consumers require analytical data, and market penetration should not be limited by lack of product testing.

In today's market, it is imperative that all industrial sand producers have an internal quality assurance and quality control program. Each load shipped should be sampled, and each load should be correlated to a “lot number.” Outside quality control laboratories generally specialize only in conducting product samples and are not equipped to provide data on mine run and processing stream samples. Therefore, industrial sand producers must have bench-scale capabilities. At a minimum, a producer should have an x-ray fluorescence (or equivalent) machine and sieving, washing, drying, and crushing facilities for sample preparation. Depending on processing techniques and markets served, internal laboratory equipment may need to include flotation, attrition scrubbing, and heavy mineral separation.

Mining

Industrial sand mining methods are contingent on deposit type. Unconsolidated deposits such as those in Colorado are mined using front-end loaders, scrapers, or bulldozers. Material is dug, excavated, and pushed to a central point. The ore-grade material is then loaded onto a truck using standard earth-moving equipment, where it then reports to a stockpile or a plant. Other unconsolidated deposits, like those found in the Atlantic Coastal Plain and on or near fluvial channels in Northern California, are mined with dredges or draglines. A hydraulic dredge uses a suction pipe to excavate the sand, which is pumped through a pipeline to surge piles or directly to a processing plant. Although draglines can be more expensive than hydraulic dredges, they are still used along the American and Yuba rivers in Northern California. The channel or tailings deposit is excavated, scalped, and placed in a stockpile. The ore-grade material is loaded into haul trucks for transportation to a processing plant.

Loosely consolidated material such as the St. Peter Sandstone can be mined using a high-pressure hydraulic monitor. Sand washed from the working face is collected in a sump, from which it is usually pumped to a dewatering/surge pile, where the material is allowed to free drain. Once drained, the sand reports to a plant.

At well-consolidated deposits such as the Hickory Sandstone, conventional drill-and-blast methods are used. Once blasted, the sandstone is “muck ed” using a front-end loader, placed into haul trucks, and transported to a primary crusher. Following crushing, the material may report to a secondary or tertiary crushing plant. The sized material is then transported to a processing plant, usually by a conveyance system.

Although uncommon, underground mining can also be used to extract competent, well-lithified sandstone or quartzite, which is extracted using conventional drill-and-blast methods. The material is then loaded by power equipment and hauled or conveyed to a plant or surge pile. In general terms, underground mining is the most expensive method, and because of the modest selling prices for industrial sand, it is usually cost-prohibitive.

Processing

Processing is what distinguishes industrial sand from common construction sand. The type of processing or beneficiation is directly related to the relative purity of the deposit and which markets the

Table 9. Historical industrial sand production in the United States and world production, t

Year	Primary Production	Imports	Exports	Apparent Consumption	Unit Value, \$/t	Unit Value, \$98/t	World Production
1985	26,700,000	73,500	786,000	26,000,000	13.58	20.58	115,000,000

supplier desires to serve. Regardless of markets, sands are, at a minimum, washed, dried, and screened. A typical process circuit would include washing to remove clay and other deleterious material. At this point, some processes may require that the material report to a rod or ball mill. After leaving the wash-and-mill circuit, a sand-water slurry is pumped to a desliming circuit in which hydrocyclones remove the slimes, which report as tailings to a thickener circuit or directly to settling ponds. The washed sand is then subjected to a coarse separation cut by hydrosizing or wet screening. The sand is further dewatered by reporting to surge piles or cyclones. Once the sand contains approximately 70% solids, it reports to attrition scrubbing, which is performed in tanks equipped with propeller-type blades. Attrition scrubbing removes clays, iron oxides, and other materials that may be on the surface of the sand grains. It also creates a fresh surface on nonquartz minerals to enhance reagent attachment, if flotation is used during further processing. Flotation is used only when high-purity quartz is required for the market. Many deposits that service filtration, oppant, abrasives, building materials, and recreation markets do not require flotation. If flotation is required, there are two types: cationic and anionic.

Some customers will accept nondried material, but all value-added markets require dry sand. Once washing and flotation (if required) is completed, the sand is dried. If a producer makes finer grade products, then those products generally report to a fluid bed dryer, whereas coarser grades generally report to a rotary dryer. Once dry, the sand is processed by dry screening. Once sized, the product reports to silos for bulk shipments, or to packaging, where the material is placed in bags or "super sacks."

ECONOMIC FACTORS

Market Trends

Industrial sand production in the United States from 1995 to 2002 remained relatively flat (Table 9), averaging 28.1 Mt (Dolley 2002). World production in 2002 was approximately 95 Mt (Dolley 2002). The United States was the leading producer, followed by Germany, Austria, France, Spain, Australia, and the United Kingdom. The

market forecast for industrial sand suggests an increase over the next several years; however, the increases are likely to be minor (1% to 3% per annum). The United States is the largest producer of industrial sand and is capable of meeting approximately 99% of the market requirements (Dolley 2002). The most significant market threats come from Mexico, Canada, China, and India.

Glass sand sales are expected to increase slightly, but sales are expected to vary from market segment to market segment. Market growth is expected in the flat glass and specialty glass markets; this growth, however, is likely to be offset by declines in fiberglass and container glass markets. Currently, a market shift to areas west of the Mississippi River is occurring in the glass industry. One major flat glass plant was recently commissioned in Oklahoma, and another plant is scheduled to be built in Washington. A large producer of container glass is also planning a significant new facility in northern Colorado.

Recycling laws enacted in many areas have affected the container glass market by increasing the supply of post-consumer cullet. To reduce costs, container glass producers have turned to cullet as a feedstock, displacing raw glass sand. Significant competition in the container glass segment has come from plastic, aluminum, and cardboard. Overcapacity in the glass-grade sand industry and the threat from packaging substitutes are likely to affect the price and sales of container glass sands. Nonetheless, since the early- to mid-1990s, container glass has experienced some growth in sales because of the increase in sales of designer alcoholic beverages.

Foundry sand demand is directly linked with automobile production. Another important factor is the amount of recycling. In the 1990s, several foundries moved to Mexico and new, state-of-the-art foundries were built there. Although some foundry sand sales were affected by the move, the high-quality sands produced in the United States are still quite competitive in Mexican markets. Foundry sand sales are also experiencing a significant threat from China. Increasing market presence in the United States of steel from Chinese foundries has displaced foundry sands produced in the United States. At the same time, it appears as though recycling of foundry

sand has increased. The overall trend in foundry sales is likely to decrease over the next decade.

Proppant sand sales are directly related to oil and gas drilling, and so the proppant market is highly cyclical. For instance, in the early 1980s the market was depressed owing to a lack of well development. The late 1990s through 2003 witnessed steady production and sales in this market—particularly in deep-gas well applications. Canada, Wyoming, and the western slope of the Rocky Mountains have seen considerable growth in gas well production. Surfaced-modified sand and white sand sales have benefited from the increase in natural gas wells, which is related to the construction of natural gas-fired power plants. Currently, there is not enough gas production to meet demand, and the major industrial sand producers are aggressively selling proppant-grade products into the gas and oil fields. Industrial sand producers are likely to continue to produce significant tons for the proppant markets. This high level of production will create production imbalances and is likely to lower pricing for glass, foundry, and abrasives applications.

The industrial sand industry has experienced consolidation, and very few new operations have come online in the last 10 years. Currently, there are 4 major producers of industrial sand, and 10 producers control 76% of the U.S. market (Dolley 2002). Additional market consolidation is likely because of the dominance of one producer. Two of the four leading producers of industrial sand are suffering from serious debt issues related to acquisitions and tort litigation due to silicosis lawsuits.

The location of production facilities will continue to drive exploration and expansions. As markets move west, deposits that were usually thought to have no market value are being revisited. However, because of low production costs and high quality, producers in the Midwest can be competitive in western markets. A significant increase in demand for industrial sand products is likely within the next 10 years in California, where two of the major producers may soon close because of the effects of urbanization and resource depletion. Therefore, it is more than likely that the western United States will be the focus of intense exploration for industrial sand.

The use of substitute materials for cast metals could have an effect on the foundry market; however, this effect could be offset by increases in the production of PV, which is used in the production of replacements for foundry sands. Because of recycling and substitution, the overall demand for industrial sand may decrease, but the value of the production may increase because of higher selling prices for value-added products such as PV.

Concerns regarding silicosis are likely to have the most significant effect on the industrial sand business. Regulatory agencies such as the Occupational Safety and Health Administration (OSHA) are working to lower the personal exposure limit (PEL) for respirable silica. If that effort is successful, consumers will consider substitution products. This will have a significant effect on the building materials and recreation market segments, where limestone could replace industrial sand. In the absence of tort reform at the federal level, silicosis claims and fears will have a significant and material effect on the industrial sand business.

Transportation

The primary methods of transportation for industrial sand products are truck, rail, barge, and ship. Of the industrial sand produced in 2002 in the United States, 64% was transported by truck from the plant to the site of first sale or use, up 2% from 2001; 34% was transported by rail, down from 35% in 2001; and 2% was transported by waterway (Dolley 2002). The availability of efficient transportation is critical to the success of any operation. Most

highly successful operations have access to both rail and truck. If production costs are low, producers can be competitive over long distances by rail. Given the uncertainties of dealing with railroads, many operators use lease cars, which limits the shipper's exposure to car availability and demurrage costs. Truck transportation is generally more reliable than rail; however, it is also more expensive. Freight contracts with guaranteed tonnages can help lower shipping costs. Many companies also treat freight as a profit center. Although there is risk in arranging and "marking up" freight, producers can make reasonable profits and can provide a service to their customers.

Production and Pricing

Industrial sand production from 1994 to 2003 has been relatively static. Total production in the United States decreased by 3.7% from 2001 to 2002. Positive or negative variations of less than 5% are the norm for this industry. Table 9 shows historical production for industrial sand. In 2002, the Midwest led the United States in production of industrial sand, with approximately 41% of the 27.3 Mt of production from this geographic area (Dolley 2002). The leading producing states, in descending order, were Illinois, Michigan, California, Wisconsin, Texas, New Jersey, Oklahoma, and North Carolina (Table 10). The combined production in these states accounted for 59% of the total U.S. production in 2002 (Dolley 2002).

In 2002, approximately 82% of the total industrial sand production was produced by 50 operations, each with production of more than 200,000 Mtpy (Table 11). Compared to 1981, the total number of producers decreased by 24 to 67. This change is likely the result of industry consolidation. The five leading producers of industrial sand, in descending order, are Unimin Corp., U.S. Silica Co., Fairmont Minerals Ltd., Oglebay Norton Industrial Sands Inc., and Badger Mining Corp.

In 2002, the average selling price for industrial sand products in the United States for all grades of industrial sand was \$20.96/Mt, up slightly from 2001 (Dolley 2002). By comparison with 1990 prices, the average selling price for combined markets increased 36.5% overall, or 3% per year. The 3% increase is approximately equal to the increase in the producer price index over that same time period. This statistic is an average and does not necessarily reflect the dynamic nature of some market segments. For example, from 1998 through 2001, certain building materials consumers in Southern California were absorbing 10% to 14% price increases per annum.

In 2002, the average price ranged from \$11.67/t for metallurgical flux to \$82.87/t for PV. Producer prices for industrial sand range from several dollars per ton to more than \$40/t, depending on the amount of processing and markets served. For some highly specialized uses, production costs can exceed \$1,000/t (Dolley 2002). In the United States, PV for use in paint, putty, and rubber had the highest average value (\$82.87/t), followed by PV for use in foundry moldings and core (\$82.43/t), swimming pool filters (\$77.07/t), well packing (\$64.63/t), municipal water filtration (\$41.83/t), PV used in fiberglass (\$40.87/t), proppants (\$40.08/t), and abrasives (\$36.86/t).

By geographic region in 2002, the average value of industrial sand was highest in the South (\$23.09/t), followed by the West (\$22.74/t), the Northeast (\$21.85/t), and the Midwest (\$18.20/t) (Dolley 2002). By comparison, in 1994 the following prices applied: the West (\$19.89/t), the South (\$19.08/t), the Northeast (\$18.57/t), and the Midwest (\$16.22/t) (Bolen 1996). Western markets command higher prices because of lack of supply and high demand. Conversely, midwestern markets garner lower prices because of overcapacity.

Foreign Trade

From 1993 to 1994, exports of industrial sand from the United States increased 7% to 1,880,000 t, whereas the value increased 12%. According to Bolen (1996), exports of industrial sand were as follows: 79% to Canada, 8% to Mexico, and the balance to numerous countries throughout the world. Based on U.S. Census data for 2002, industrial sand exports decreased 8.4% to 1,410,000 t, whereas the value decreased by 11%. Most of the decrease in

exports is attributable to the sharp declines in shipments to Asia and Europe (Dolley 2002). Export distribution in 2002 for industrial sand produced in the United States was as follows: 39% to Canada, 35% to Mexico, 12% to Japan, 4% to Europe, and the remainder to South America and other destinations. According to Dolley (2002), the average price of exports decreased to \$103/t in 2002 from \$106/t in 2001. Export prices vary widely by region, with higher grade prices of exported material to Europe averaging \$585/t and the rest of the world averaging \$81/t.

Imports for industrial sand, from 1993 to 1994 data, dropped by 50% to 22,000 t, valued at \$1.8 million. Conversely, imports in 2002 rose to 250,000 t, which was an increase of 45% compared to imports in 2001 (Dolley 2002). Industrial sand imports vary greatly from year to year, and are, as a whole, insignificant in relation to total U.S. consumption. The variations are generally related to the emphasis of importers on niche markets. For example, in 2002, several thousand tons of filtration-grade and proppant-grade Chinese sand was imported for use in the Bakersfield and Sacramento areas of California. Because of quality issues, the sand was rejected for use; therefore, Chinese sands were not imported in 2003. In 2002, Mexico supplied 72% of the industrial sand imports, which averaged \$6.66/t.

World Review

World production of industrial sand in 1994 was estimated to be approximately 111 Mt, up nearly 5% over 1993 data (Bolen 1996). The United States was the leading world producer (and consumer) of industrial sand, followed in descending order by the Netherlands, Germany, Austria, and France (Table 12). In 2003, world production was estimated to be 94 Mt (Dolley 2002). The United States continued to be the leading producer (and consumer), followed by Germany, Austria, France, Spain, Australia, and the United Kingdom, in descending order. Most countries in the world produce

some industrial sand because of requirements for foundry and glass applications. World production continues to be difficult to track. Many countries report grades differently; therefore, obtaining reliable data is problematic.

China and India continue to pose a significant threat to U.S. producers. Currently, limited amounts of industrial sand are imported to the United States from India and China. This is due primarily to the relatively low price for industrial sand and quality issues that have plagued Chinese sand.

Government Controls and Restrictions

Silicosis and Regulatory Restrictions

The most significant challenges presented to the industrial sand business in the United States are tort litigation related to silicosis claims and continued attempts by state and federal regulatory agencies to reduce PELs of respirable silica. In 1986, the International Agency for Research on Cancer (IARC) classified respirable crystalline silica as Group 2A, Probably Carcinogenic to Humans (IARC 1987). In 1996, IARC reviewed additional data and recommended that quartz and cristobalite be listed as Group 1, Carcinogenic to Humans. Following the publication of the IARC data in 1997, several state and federal regulatory agencies began attempts to closely regulate respirable silica.

OSHA has established 0.1% of a suspected carcinogen as the maximum amount any product may contain before its sale must be accompanied by a health hazard warning (Hazard Communication Standard). To comply with the Hazard Communication Standard, and other state (e.g., California Proposition 65) and federal regulations, products must be evaluated for crystalline silica content at a threshold of 0.1%. Several analytical methods have been developed to determine crystalline silica in a variety of products. However, accurately quantifying small amounts of crystalline silica in a mixture of accessory minerals and unknown states is difficult. Of all of the analytical techniques, x-ray diffraction (XRD) has the greatest

potential for accurately identifying the polymorphs of crystalline silica and determining each at the 0.1% threshold (Miles 1999). XRD techniques are nondestructive, thus allowing analyzed samples to be preserved. XRD is neither inexpensive nor routine, however, and care must be taken to identify the crystalline silica polymorphs with certainty. The most significant issue is spectral overlap with other minerals. It is important to employ quality laboratories with specific experience in identifying crystalline silica. It is not uncommon for a laboratory that lacks crystalline silica experience to inaccurately identify silica polymorphs. This leads to a significant concern with respect to the regulation of crystalline silica.

For a number of years, inhalation of crystalline silica for extended periods has been known to cause, in some workers, a potentially disabling and sometimes fatal respiratory disease known as silicosis. Silicosis is a preventable occupational illness with a specific diagnosis. Outside the occupational setting, there is no scientific evidence that exposures of the general population to crystalline silica in the ambient air have caused (or would be expected to cause) silicosis. The number of new silicosis cases in the United States has fallen dramatically over the years. The Centers for Disease Control and Prevention (CDC) data suggest that silica-related mortality declined by an order of magnitude since 1969, from 1,800 related cases to fewer than 180 cases in 2000. This can be attributed to improved ventilation and the use of proper personal protective equipment (PPE). Moreover, because there is a significant lag period following exposure, new cases of chronic silicosis that are diagnosed today most likely are attributable to exceedances of the PEL that occurred 10 to 20 years ago or more. While exposures to crystalline silica have been reduced in recent decades, data collected by OSHA, the National Institute for Occupational Safety and Health (NIOSH), and the Mine Safety and Health Administration (MSHA) indicate that overexposures continue to occur in the occupational setting. For example, 37.8% of the samples collected for respirable quartz testing by OSHA in manufacturing exceeded the PEL in 1998, and 38.3% exceeded the PEL in 1999. The comparable exceedances for metal/nonmetal mining were 6.7% in 1998 and 8.0% in 1999 (NIOSH 2002).

The current OSHA/MSHA PEL for quartz (the most abundant mineral in industrial sand) equates to 0.1 mg/m³ as an 8-hr time-weighted average. In March 2004, the California Office of Environmental Health Hazard Assessment in association with the California Environmental Protection Agency (EPA) Science Review Board began considering recommending a Chronic Inhalation Reference Exposure Level (REL) for crystalline silica of 3 µg/m³, along with a Chronic Toxicity Summary document in which the recommended REL is derived. Although the proposed REL was not scientifically derived, California is still considering regulating crystalline silica at levels that, in many localities, are below the ambient crystalline silica levels.

For a variety of industry sectors, including industrial sand producers, it is unlikely that a PEL below the current permitted regulatory limits would be technologically or economically feasible. This is particularly true given that PELs are enforced on a single-shift basis, even if long-term average exposure on multiple shifts is significantly below the PEL. This approach to enforcement effectively requires producers to maintain the workplace environment at a fraction of the PEL to ensure that a single-shift measurement does not result in a citation.

If regulatory agencies are successful in lowering the PEL or implementing a REL below ambient crystalline silica levels, then it would be technologically and feasibly impossible for industrial sand producers to comply. Further, lowering the PEL would create

serious and relevant concerns with respect to the accuracy and reliability of the data.

Crystalline silica was listed in the regulations for MSHA and OSHA in 2004. It is likely that industrial sand producers will continue to be the focus of ever-increasing regulation. In addition to increased regulation, industrial sand producers have been the focus of litigation regarding silicosis. One significant silica litigation risk issue is the regulations covering silica. Regulations establish requirements and create enforcement risks for the industry, but they also create assumed corporate knowledge of risk and standards of care that become evidence in tort liability cases. Industry monitoring groups estimated that 35,000 new silicosis claims would be filed by October 2004, with a focus on producers in Mississippi, Texas, Ohio, and Pennsylvania. Recent tort reform laws in Mississippi and Texas, and silica-specific legislation passed in Ohio, are expected to prompt acceleration in claims in those states and create a trend of litigation in other states. In the spring of 2004, the Minnesota Supreme Court issued a decision restricting the conventional "sophisticated user" defense used by industry. Therefore, it is reasonable to expect more silica-related claims in Minnesota and in other states where the sophisticated-user defense has been used by industry.

It is also important to note that several insurance providers to the industry are circulating "silica exclusions" for all new policies and renewals. Therefore, claims going forward from renewal will not be covered by insurance. In the absence of tort reform at the national level, it is likely that this trend will increase significantly. Defending silicosis litigation has the potential to be the most relevant financial concern for the industrial sands business.

Land Use and Environmental Restrictions

Urbanization continues to pose a material threat to current operations and exploration targets. High-density housing threatens existing operations all over the United States, and new homes are encroaching on or condemning known resources. This is a concern in the western United States, particularly California. High-density, high-value housing subdivisions are being developed close to the permit boundaries of the two largest producers of industrial sand in California.

The mineral extraction industry, for the most part, has poor relations with local communities, and it is becoming increasingly more difficult to permit operations on both public and private land. As development continues and environmental regulations become more stringent, operators will have to increase the transparency of their operations and work in partnership with community and environmental groups. Although operators are not likely to be successful in deregulating the industry, operators can increase their credibility in the community by operating clean, safe, and efficient operations. If practical, operators should create community advisory boards and meet with them regularly. It is also important to integrate community comments into the management of an operation. Many industrial sand plants and extraction sites are located close to population centers; therefore, working in partnership with stakeholders is the only way that producers can enjoy overall success in the current regulatory environment. As regulation increases, operators must identify issues and work with the community and the regulatory agencies to minimize risk to the environment, stakeholders, and their operations.

Since 1998, aboriginal land claims in the United States and Canada have increased. In general terms, Native Americans claim that their land was illegally taken from them, thus mineral extraction operations have committed trespass. As plaintiffs, the Native American tribe or pueblo generally requests compensation for loss of revenue and a return of the land. It is difficult to predict how the

courts will decide in these cases, but an unfavorable decision for the industry would create a judicial precedence that would be problematic for the industry as a whole. Any operation in the western United States that operates on patented land or public land is at risk. It is difficult to predict what, if any, overall effect aboriginal land claims will have on the industrial sands business. However, it is a risk that all operators should evaluate.

High Pure and Ultra-High Pure Quartz

John W. Schlantz

INTRODUCTION

Quartz, or silica sand (SiO_2), has enjoyed a multitude of industrial uses, from low-end markets of construction material to mid-range markets of glass, ceramics, and fillers to high-end, high-tech uses such as electronics, optics, semiconductors, lighting, infrared, specialty glass, fiber optics, and the computer and communications industries. *Fused silica*, or *fused quartz*, is the common term that applies to silica in most of these high-tech markets.

In the first half of the 20th century, quartz for higher end markets was hand-cobbed from crystal or lump deposits. The most sought-after material came from the Lascus deposits in Brazil, which had such purity that it was considered a strategic supply for early communications (radio), especially during World Wars I and II. Later, advances in beneficiation technology enabled the mass production of quartz to various levels of purity, depending on the nature of a quartz deposit, the natural characteristics of the quartz, and the ultimate end use.

IMC Corp. began mass production of high pure and ultra-high pure quartz in the Mitchell County/Spruce Pine area of western North Carolina in the late 1950s. These quartz products were marketed under the trade names Quintas (high pure) and Iota (ultra-high pure quartz). Because of their success, the two grades are often referred to by these trade names in the industry. Over the years this operation changed hands several times, and Unimin Corporation now owns and operates it.

Because of advances in many high tech industries, and the relative scarcity of supply, the use and price of high pure and ultra-high pure grades have grown accordingly, creating a high level of interest in finding suitable deposits capable of producing equivalent raw materials or superior products.

MITCHELL COUNTY/SPRUCE PINE QUARTZ

The mass production of high pure and ultra-high quartz products in the Mitchell County/Spruce Pine district of western North Carolina by Unimin Corporation supplies the majority of the world market. The Feldspar Corporation (Zemex Corporation) also produced high-grade quartz, but on a limited basis. Feldspar Corporation entered the quartz market in the early 1980s and built the second quartz plant in Spruce Pine. Because of challenges in the development of markets, however, the operation never became profitable. Zemex sold the operation to Unimin in the early 1990s, giving Unimin an exceptionally strong position in the market, which they maintain today.

Feldspar and Mica Recovery

High pure and ultra-high pure quartz in North Carolina originally were by-products from the mining and recovery of mica and feldspar from the vast reserves of the granitic pegmatite referred to as alaskite. Initially, both Zemex and Unimin mined the same alaskite ore body, which has the approximate composition of 60% to 65% feldspar; 20% to 25% quartz; 5% to 10% mica; and 5% to 10% iron minerals (such as garnet and biotite). The process to recover feldspar and mica (Figure 1) has been used for more than 50 years.

The process begins with run-of-mine ore undergoing primary and secondary crushing (jaw and cone crushers, respectively) to approximately $-1/2$ in. The crushed ore is reduced further to 20 mesh by rod and ball milling in closed circuit. It then is washed through a series of cyclones to remove fines <200 mesh, providing a flotation feed of 20 × 200 mesh.

Flotation first recovers mica and consists of conditioning with amine-type collectors in an acid circuit. A rougher concentrate is produced that is subsequently cleaned to produce a concentrate at +90% mica content.

Tailings from the mica flotation report to another acid circuit with a petroleum sulfonate collector to remove the iron-bearing minerals, which, with the exception of the fines, is the only waste product generated. The clean pulp finally is floated with hydrofluoric acid and amine for feldspar concentration. The feldspar is filtered and dried, then sold directly to the glass industry or processed further with magnetic separation and fine grinding for the ceramic and filler industries.

Quartz Processing

Tailings from the feldspar flotation serve as feed to the quartz-processing plants. Producing the high pure grades of quartz from these tailings was a very attractive prospect to both companies, especially Feldspar Corporation. For many of the early years of these operations, Feldspar sold these tailings as low-grade construction products for a dollar or two per ton or disposed of them in tailings dumps. The companies actually were looking for ways to dispose of the tailings, and the potential to produce value-added products from "waste" is always compelling.

Because feldspar is the primary product and quartz is a by-product, the feldspar flotation leaves residual amounts of all minerals in the quartz tailings, and these must be thoroughly removed to produce the purity required for the high and ultra-high pure grades. These processes are considered proprietary and cannot be discussed

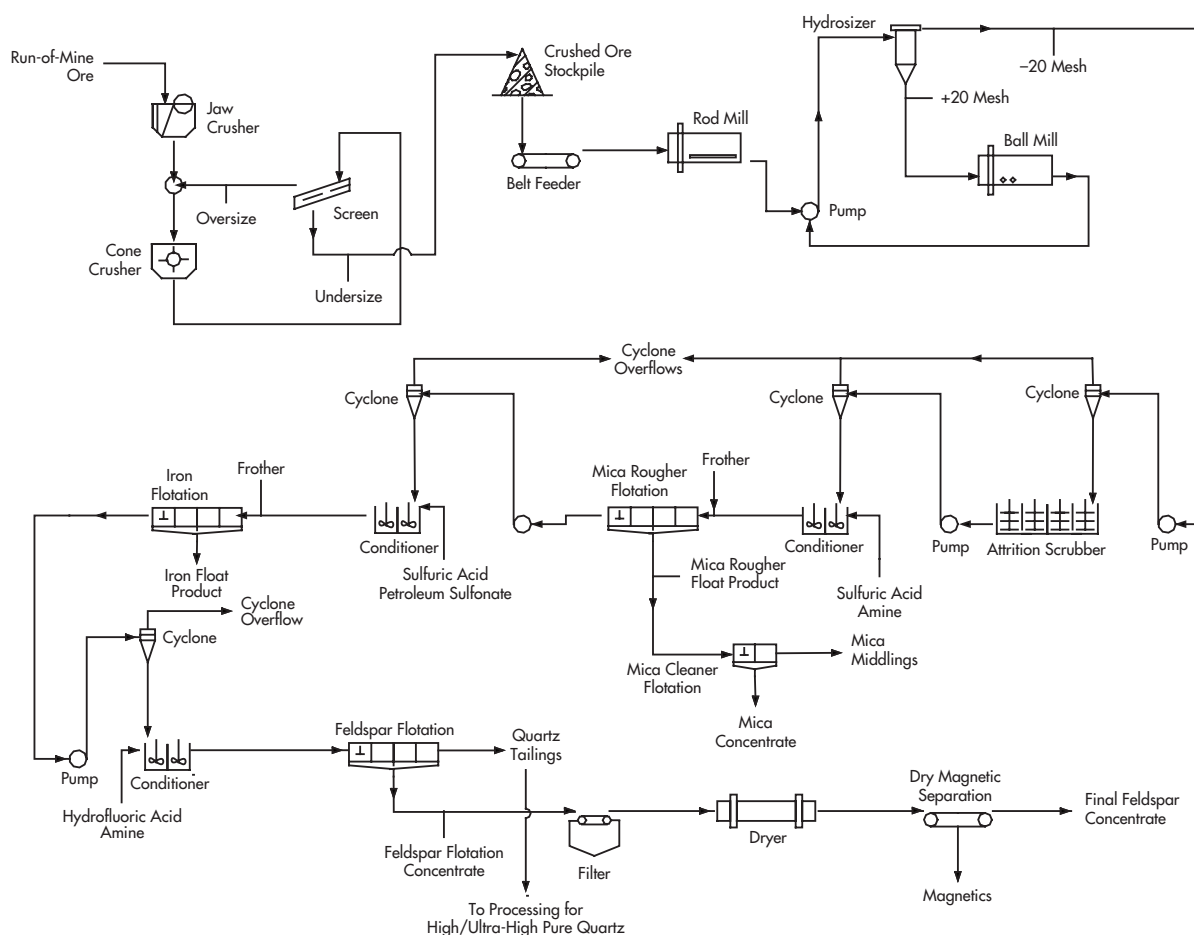

Figure 1. Schematic flowsheet of typical alaskite flotation (mica, iron, and feldspar flotation)

in this chapter; a general statement regarding the processing in to higher grades, however, would show that the high pure quartz, or Quintas grade, typically is produced through additional physical separations whereas the ultra-high pure, or Iota grade, will require additional chemical processing methods. The unit operations to which the final quartz is subjected can vary, depending on the degree of purity required for given markets.

The Unimin Corporation gained a significant advantage over the Feldspar Corporation in the late 1980s with the purchase of the old Harris Mining Company property. This operation mined and processed mica and kaolin for many years, and Unimin purchased the property for uses other than mining (i.e., water discharge permits). They soon discovered, however, that quartz in the soft or weathered Harris alaskite deposit could produce grades superior to those extracted from the hard alaskite ore.

Although Unimin continues to mine and process quartz from the alaskite ore, the development of the Harris deposit raised the standard of purity and led to the development of higher-grade Iota products. Even though this material goes only into highly specialized markets (i.e., computer chip manufacturing), this development was a factor in Feldspar Corporation's decision to abandon the quartz business.

Unimin today controls the majority of the world market for high pure and ultra-high pure quartz. Feldspar Corporation continues to supply small amounts, but only in the high pure form that is sold to a few select customers who process this quartz into higher-

grade products. Hand-cobbing operations in some developing countries such as India produce small amounts, but they do not represent significant competition to Unimin's Spruce Pine operations.

EXPLORATION AND DEVELOPMENT

Logically, exploration efforts tend to focus on similar alaskite deposits, but the geology of the pegmatite in the Spruce Pine area remains somewhat of a mystery with regard to the purity of the quartz. The author personally is aware of consulting geologists working exclusively in the quartz industry, and their ideas about where to look and what to look for change frequently. Quartz with high potential for development has been found in both pegmatite and vein deposits.

The author also has evaluated literally hundreds of samples from throughout the world. These samples were submitted by qualified geologists and, more often than not, the material was inferior in quality. In addition, extensive work was done comparing various chemical and elemental properties to find a correlation between quartz with high-grade properties and those defined as unsuitable, with inconclusive results.

Many theories and ideas have been offered over the years to explain the exceptional purity of the Spruce Pine quartz deposits. These range from extreme weathering conditions to remelting theories. The weathering theory received considerable attention: the belief is that such weathering leached out the majority of contaminants found in typical granitic pegmatites. Therefore, considerable

emphasis was placed on this type of weathered deposit for exploration. On the surface, this line of thought had some logic to it because the Harris deposit certainly underwent extreme weathering and it produces the purest quartz products. Given the type of “contaminants” that disqualify most quartz deposits, however, this theory cannot account for its total purity.

Contaminants found on the surfaces of quartz particles, or liberated from the quartz crystal, typically can be removed through a variety of processes; it is these contaminants that would be removed via the weathering process. Those contaminants found within the quartz crystal itself in trace amounts are those that current technology cannot remove. These are present either as interstitial cation impurities or as substitutions for the silicon atoms in the center of the tetrahedral crystal structure of the silica.

Commonly, quartz contains aluminum (Al^{+++}) and ferric iron (Fe^{+++}) substituting for silicon (Si^{++++}) in the tetrahedral site; balance is achieved by ions such as sodium (Na^+), potassium (K^+), lithium (Li^+), and hydrogen (H^+) in the interstitial positions. The dominant contaminants, or those most likely to enter the quartz structure, are not necessarily those with the highest affinity or structural fit but rather those that are the most abundant in the geological environment. Most quartz does not contain a large amount of such impurities except when compared to those found in Spruce Pine.

Impurities of another type occur as inclusions in the quartz grains, and these can be solid or liquid and/or gas inclusions. Common solid inclusions are rutile, mica, and garnet. Liquid and gas inclusions can contain CO_2 , N_2 , H_2O , ammonia (NH_3), SO_3^- , F_2 , Cl_2 , Na^+ , K^+ , and Li^+ .

Liquid and gas inclusions occur when solutions or gas become entrapped during the initial crystallization of quartz or later during secondary growth. Solid or mineral inclusions typically occur either by mechanical enclosure in quartz grains during initial crystal formation or by exsolution after crystal formation.

It is commonly believed that the Spruce Pine quartz is the purest in the world, and it is certainly superior to any other mass-produced quartz. Its purity comes primarily from its lack of trace impurities. It is well known that impurities and structural defects in quartz are typically greater in quartz formed at lower temperatures and pressures. One might postulate, therefore, that the Spruce Pine quartz was formed under high temperatures and high pressures. Because this quartz is classified as primary quartz, it also is theorized that the parent magma did not have an abundance of trace elements in its environment available for substitutions and was probably lacking in H_2O . Relatively high quantities of calcium and plagioclase feldspar found in the alaskite suggest evidence of such conditions. Atypical crystallization temperatures and pressures, magma water content, lack of contaminating elements in the enriched magma during quartz formation, and other factors are probably responsible for the high level of purity of these quartz deposits. These circumstances are responsible for classifying the Spruce Pine quartz as unique.

After evaluating numerous samples, and given the lack of intensive geological data on quartz deposits throughout the world, the author believes that finding a suitable raw material may be a simple case of “hit or miss” or “trial and error.” In fact, the quality of Spruce Pine quartz was “stumbled” on: neither company realized its potential for many years. Today many evaluations for these quartz products result from evaluating deposits for other mineral values; the quartz in samples from these deposits may show some initial potential for upgrading.

Given the unique example described, suggesting guidelines for high pure quartz exploration is, at the least, difficult. The best sug-

Table 1. Elemental limits—initial qualification, maximum ppm

Quartz Product	Fe	Al	K	Na	Ca	Li	Mg	Ti
High pure	20	250	80	100	50	2	30	5
Ultra-high pure	1.0	15.0	2.0	2.0	2.0	0.5	0.5	1.0

gestion is to search for quartz that has no inclusions and no contaminants substituting in the actual SiO_2 crystal matrix. To produce the purity required, all contaminants must be liberated from the quartz or from the surfaces of individual grains. The explorer, therefore, should investigate deposits that appear, on microscopic examination, relatively clean and clear. The deposits should then be compared with quartz from current operations with data indicating potential grades, if available. Unfortunately, the only way to determine conclusively the true quality of any quartz is large-scale testing.

Any final judgment on quartz purity based on feed analysis, or data generated from partially or unbeneficiated material, could lead to false conclusions. The Spruce Pine material is a good example. Because it contains high amounts of feldspar, mica, and other minerals in the ore, analysis of a Spruce Pine run-of-mine sample would not indicate the quartz potential. The same could be said for the actual quartz tailings from these operations that serve as feedstock for quartz processing, because these tailings typically contain up to 5% to 10% feldspar and residual mica, biotite, and garnet. Only after these had been removed completely did the true potential for quartz become apparent.

Development/Evaluation

After a suitable source of raw material has been found, its evaluation, although highly objective in the initial phases, can become rather complex and time consuming. Once the material has initially qualified and its performance has been determined, furnace trials must be conducted with potential customers to certify the material for their use.

Because end uses for quartz products vary, exact product specifications are ultimately defined by product performance as determined by a potential consumer. Some typical elemental contaminant limits, however, can be applied initially to evaluate the quartz or control the process.

Table 1 lists typical limits on contaminants. It does not include all the elements that would disqualify a quartz resource, but it serves as a basis for further evaluation. Although many describe quartz in terms of percent SiO_2 , this often is misleading, especially in the ultra-high pure grades. A quartz product could be described as 99.999% SiO_2 but still contain trace elements on a level measured in parts per million that could hinder the performance of quartz in its end use.

The typical evaluation process begins with bench-testing the raw material to produce relatively small samples of high pure and ultra-high pure products. (The ultra-high pure grades are produced only if the high pure product compares reasonably well with the elemental guidelines in Table 1.) If the chemistry is acceptable, the material is evaluated to see how it actually will perform; this defines its commercial viability. This phase of the evaluation is almost always market specific. A common method is to produce a fused quartz product (e.g., crucibles) and examine it for flaws.

Once chemistry and fusion are deemed satisfactory, furnace trials certify the quartz. This is done by the producer using the quartz products and requires the production of bulk concentrates (sometimes up to 10 st or more) on a pilot-plant scale under very tightly controlled and contamination-free conditions. Few commercial or academic research laboratories have the expertise and

Table 2. Typical product specifications, maximum ppm

Product	Fe	Al	K	Na	Ca	Li	Mg	Ti
High Pure Quartz

* na = not available.

experience (e.g., North Carolina State University [NCSU] Minerals Research Laboratory, Asheville) to produce such bulk concentrates that have passed the strenuous qualifying process.

Although actual fusion performance is the ultimate evaluation factor, some researchers use the high standard set by Unimin's highest Iota grades to assess the quartz on an elemental basis. Iota grades contain exceptionally low aluminum (<7 ppm) and other elements are in the range of those listed in Table 1 and produced from the Spruce Pine alaskite. Disqualifying a material based on direct comparison to the Iota products may be a mistake, because relatively lower-grade products (10 to 15 ppm Al) can be introduced into the market with success. To support this, Table 2 lists some actual marketed products along with their chemistries. Though Iota 7 is used as a comparison tool, it should not be the only factor in the final evaluation process.

Evaluation Costs

It is difficult to place an exact cost on the evaluation process because all deposits and projects are unique; some estimates can be offered, however, based on experience. The initial bench evaluation can range from \$1,500 to \$5,000 per sample, which includes the production of a small amount of quartz, chemical analysis of the high pure quartz product, and possibly leaching, chlorination, and final chemical analysis of the ultra-high pure product.

The most cost-intensive items are the chemical analysis and leaching. Few laboratories can perform accurate chemical analysis on these products. An extensive search for suitable raw material can involve evaluating many samples, and the evaluation can become expensive, if not prohibitive.

Pilot-plant testing that produces bulk concentrates of high pure quartz costs \$40,000 to \$100,000, depending on the amount and type of processing required and the tonnage produced. Additional costs would be incurred should these bulk concentrates require processing to the ultra-high pure grades.

It is important to realize that noncontaminating conditions are critical during both bench scale and pilot-plant scale tests. The simple touch of a human hand or a cough can contaminate a sample and yield erroneous results regarding product grade.

MARKETING

In most industrial minerals ventures, a market study is key in determining the potential use of the product, size of the market, price of the commodity, transportation costs, profit estimations, potential by-products, and competition (not only from other suppliers but also from other materials). In the high pure quartz market, the specialization and anticipated profit margins ensure a high unit price,

so transportation is usually not a factor. Competition comes only from other suppliers, because there are no known substitutes.

A marketing strategy in the quartz industry is essential, as is a competent sales staff, which should be included in any operating costs. The sales and marketing staff should have a thorough understanding of the potential markets, and finding such a team may be a significant challenge because experienced people are not readily available.

A common mistake in the marketing strategy of high pure and ultra-high pure quartz is neglecting the wide variety of high pure quartz markets. Many promoters and developers focus their attention on producing the best quartz available, attempting to surpass the quality of Iota grades; the overall ultra-high pure quartz market, however, is relatively small (albeit with very large profit margins). Developing a high pure product with reduced production costs may be necessary to create volume sales from any proposed plant.

Even with the capability of developing a high pure product and its markets, total volume of production at the plant will be comparatively small. Any operation under serious consideration would be specifying a plant to produce 35,000 to 50,000 tpy of high pure quartz product, with perhaps 10,000 to 15,000 t earmarked for eventual ultra-high pure quartz production. This total yearly tonnage is equivalent to what some conventional mining operations process in a day.

The high pure markets would include applications in specialty glass, glass tubing, lighting, decorative glass, and opticals, among others. These niche markets are easier to penetrate than the markets for electronics, computer applications, and fiber optics. Therefore, a marketing approach should consider the high pure quartz products that conceivably can create a more immediate cash flow. The plant can survive financially on this volume while inroads are made in the harder-to-penetrate, ultra-high pure quartz markets.

These niche markets are small in terms of the volume required by individual consumers, but there are many of them, so the total volume (overall tonnage) of high pure quartz that can be moved into these niche markets can be significant. This is further justification for employing a well-trained sales staff.

Marketing the products should be done early in the evaluation process, especially for the ultra-high pure products. Relationships with potential consumers are critical given the rigorous certification process. Having one or two customers involved at the beginning is a tremendous advantage and can lead to timelier furnace trials, assistance in product development, additional expertise, and perhaps funding for the operation (i.e., joint ventures). The best-case scenario would be sales commitments from at least one high-end user once production begins.

It is important to understand that these high-end users stand to lose significant revenue if a batch of quartz fails to perform as expected. Therefore, customers are very cautious and reluctant to change suppliers, but they are seldom closed to the idea.

COSTS

Because of contamination concerns and the need for special materials of construction, a high pure quartz plant is costly to build, operate, and maintain compared to typical mineral processing plants. In the early 1980s, it is estimated that at Feldspar Corporation's quartz plant cost \$15 to \$20 million to construct and was designed to process 60,000 tpy of quartz with a projected production capacity of 35,000 tpy. A similar plant today would cost upward of \$50 million. Unit costs per ton of product would have to be high given the relatively low production volume.

Potential profit margins on the high pure and ultra-high pure quartz products can offset these capital costs with rapid return on investment. High pure quartz today is demanding \$500 to +\$1,000/t in the marketplace, whereas the ultra-high pure products sell for \$2,000/t to more than \$10,000/t (and some are rumored to be as much as \$15,000/t). The final sales price depends on end use and product quality. Again, the ultra-high pure market is considerably smaller, but with the high unit price of the high pure products, it is obvious why both markets need to be taken advantage of. For comparison, this is much more attractive than the \$1.50/t for silica sand as construction materials.

Production costs, which depend on process parameters and quartz recovery, are difficult to predict. High pure quartz, however,

could probably be produced for \$300 to \$600/t, whereas the ultra-high pure product would most certainly be double that at \$600 to \$1,200/t. Given the relatively high sales price, it is obvious that a high profit margin would exist. The pricing structure is due to today's market conditions, but additional suppliers could alter this; there is still, however, opportunity in the industry for competitors to enter the market and maintain a high profit margin.

These costs are estimates based on experience and should not be used to justify any quartz venture. A detailed economic evaluation is recommended and should be based on specific ore grades, process parameters, and a detailed market evaluation. It is important to realize that the Spruce Pine operations produce quartz as a by-product, and mica and feldspar production absorb a portion of the production cost (for example, mining and crushing costs), offering the producer a significant production cost advantage.

PRODUCTION AND FUTURE TRENDS

Given the highly secretive nature of the high pure quartz industry and the small number of producers active in the marketplace, no production figures are available and they are unlikely to ever be published. A select few companies enjoy an exceptionally strong position in the market and would certainly like to see it remain as such.

Future market conditions and technological advances may demand increased quantities and higher purity, which may bring synthetic silica into play; but thus far there is little or no evidence of such activity.

Specialty Silica Materials

Stanley T. Krukowski

Specialty silica materials, as defined in this chapter, are rocks that consist predominantly of silica (SiO_2) and are produced as chunks, round pebbles, and sawed or trimmed blocks and other shapes for nonconstruction applications. Rock types are quartzite, sandstone, novaculite, flint, chert, and vein quartz. Other terms used commercially include jasper, silix, lascas, and rock crystal.

In its *Minerals Yearbooks*, the U.S. Geological Survey (USGS) reports the production and consumption of some specialty silica materials under several headings. Quartzite, sandstone, and novaculite use in abrasives are covered by the USGS under Abrasive Materials. Lascas, a type of vein quartz used in growing synthetic quartz crystals and in fusing applications, is discussed under Quartz Crystal. Silica gravel used in manufacturing silicon metal and ferrosilicon, as metallurgical fluxstone and as a filtration medium, is covered under Industrial Sand and Gravel. This overview consolidates information on these and other specialty silica materials.

GEOLOGY

Sandstone

Sandstone is a sedimentary rock comprising predominantly quartz grains bound together by argillaceous, calcareous, ferruginous, or siliceous cements. Common detrital impurities are feldspar, mica, and a wide variety of heavy minerals such as ilmenite and kyanite. The purest quartz sandstones, also called quartz arenites, consist almost entirely (i.e., >95%) of fine to medium, well-sorted, and well-rounded quartz grains. They are more common in near-shore facies than in deepwater facies. The degree of induration varies from tightly cemented, hard, and tough sandstone to loosely consolidated, friable rock. Induration usually increases as grain size decreases. Color depends largely on the cementing material present. Most sandstones used in specialty applications in Canada, England, Germany, and the United States are Cambrian, Silurian, or Pennsylvanian (Carboniferous) in age and range from 3 to 85 m in thickness. Cambrian age sandstones usually rest unconformably on an eroded Precambrian surface.

Formations of medium- to coarse-grained sandstone mined for specialty applications contain lenses of round quartz pebbles or thicker beds of quartz pebble conglomerate. Pebbly zones commonly are found as long, narrow bands deposited in channels cut by streams into underlying rock. Pebbles range in diameter from 0.3 to 8 cm, and conglomeratic beds range in thickness from 15 to 90 m.

Quartzite

Quartzite is a metamorphic rock derived from sandstone and is distinguished from sandstone by its fracture. Sandstone breaks along grain boundaries, whereas quartzite is so well indurated that it breaks across constituent grains. Orthoquartzite, the metamorphic equivalent of quartz arenite, consists of quartz grains cemented by silica and commonly exhibits relict sedimentary textures (Murphy and Brown 1985). In metaquartzite, quartz grains no longer are discrete particles but have coalesced into a network of interlocking crystals as a result of recrystallization during metamorphism.

Quartzites range in thickness from 100 to >1,200 m and occur mostly in Precambrian- to Silurian-age formations. The rock can vary widely in texture, friability, color, and chemical purity depending on the type of cement, grain size, and mineral composition of the original sandstone, and the intensity of metamorphism. Quartzite derived from argillaceous sandstone often contains sericitic partings, which may raise its alumina and alkali content above acceptable limits, causing it to crush into undesirable slabby pieces. Fine- to medium-grained, massive quartzite containing little or no feldspar, mica, or carbonate mineral impurities tends to be dense, hard, and tough; it tends to crush into sharp, brittle, angular fragments. Its chemical purity can range from 96.0% to 99.8% SiO_2 . Coarse-grained quartzite tends to be less pure and more friable, particularly if the cement is argillaceous or calcareous. Colors range from white and gray-white to shades of red, pink, purple, blue, and orange. Compressive strength can vary from 1.52×10^5 to 4.96×10^5 kPa, and the specific gravity of most quartzites is between 2.65 and 2.70.

Novaculite

The term *novaculite* is derived from the Latin word *novacula*, meaning razor hone (Steuart, Holbrook, and Stone 1985). Novaculite is a very dense, hard, fine-grained, homogeneous, and highly siliceous sedimentary rock with Mohs hardness of 7 and specific gravity of 2.63 to 2.64. Its color varies from white to gray, light brown, bluish, or black; it is translucent on thin edges; and it breaks with an uneven conchoidal or subconchoidal fracture (Holbrook and Stone 1979). It resembles chert, although its fracture surfaces are finely granular or gritty in comparison to the smooth fracture surfaces of chert and flint (Sholes 1977). The luster of novaculite varies from waxy to dull, the latter resembling unglazed porcelain. Its chemical purity can exceed 99% SiO_2 in the form of microcrystalline or cryptocrystalline quartz.

Perhaps the most distinguishing characteristic of novaculite is its texture. Rock that has been little affected by thermal metamorphism is made up of anhedral quartz grains. By comparison, rock that underwent thermal metamorphism—for example, near Hot Springs, Arkansas, and Broken Bow, Oklahoma consists of coarser, polygonal or polyhedral, triple-point crystals or sharp-edged blocks of quartz 5 to 20 μm in diameter (Keller, Stone, and Hoersch 1984; Steuart, Holbrook, and Stone 1984). The porosity of novaculite from near Hot Springs ranges from 0.07% to 0.25% for the Hard Arkansas Stone variety, which has a waxy luster, and from 5% to 16% for the Washita Stone (Ouachita Stone, or Soft Arkansas) variety, which has a porcelanic appearance (Harben 1983). Washita Stone contains rhombic cavities from which calcite or other carbonate mineral were dissolved. Broken surfaces of Hard Arkansas Stone are smooth, whereas those of Washita Stone are rough. Beds of Washita Stone contain fewer joints and quartz veins; the stone becomes tougher (less easily fractured) when exposed to weathering.

The Arkansas Novaculite Formation lies conformably between the older Missouri Mountain Shale and the younger Stanley Shale. It attains a maximum thickness of 290 m and consists of upper and lower novaculite members interbedded with three units of chert and shale. The upper member is Mississippian in age and has a maximum thickness of 55 m. It is a white to light gray or blue-black massive calcareous rock that contains as much as 30% carbonate minerals where it is unweathered. It weathers to beds of soft, powdery tripoli that reach up to 12 m in thickness. The purer lower member ranges in thickness from 15 to 135 m, is Devonian in age, and is a white to light gray or light brown massive rock that is cut extensively by joints oriented normal to bedding. It is slightly calcareous near its base where dissolution of calcite rhombs produced a distinctive whetstone texture (Steuart, Holbrook, and Stone 1984).

Vein Quartz

Massive quartz for specialty applications is obtained from the central core of zoned pegmatites and from veins, dikes, and plugs within sedimentary, igneous, or metamorphic host rocks. Host rock formations usually range in age from Precambrian to Jurassic. It is believed that most deposits formed by hydrothermal processes, although not all are located near granitic intrusions. They occur as fissure and cavity fillings and, less commonly, as metasomatic replacement bodies.

Pegmatites associated with granitic intrusions generally yield very pure quartz, especially in the case of microcline pegmatites devoid of muscovite and rare-earth oxides; but they have a well-developed quartz core with druse cavities. Cores of such pegmatites commonly contain abundant fluid inclusions that render the quartz unsuitable for fusing into clear quartz glass. Massive quartz veins of hydrothermal or metasomatic origin may have a zoned structure consisting of several generations of quartz crystal growth. The oldest generation is coarse grained and usually contains abundant fluid inclusions; the younger generations are finer grained and purer; and the youngest generation consists of crystals in druse cavities. Wall rocks of such veins usually are leached, sericitized, or chloritized. The size of cavities containing quartz crystals is directly proportional to the intensity of wall rock alteration. In general, the more chlorite a vein contains, the purer the quartz within the vein. Hydrothermal veins that were metamorphosed, or segregated from country rocks during regional metamorphism, tend to be free of fluid inclusions and, therefore, tend to yield fusing-grade quartz (Kuzvart 1984).

Primary quartz deposits in Brazil occur in the form of veins, pipes, pockets, stockworks, and composite lodes confined to sili-

ceous host rocks. They are found mostly within crossbedded sandstone and quartzite of Late Precambrian age and along the contact between Precambrian granite and Silurian shale. Veins and pockets were emplaced in early Paleozoic, probably Silurian, time (Bates 1960). They are made up mostly of very large crystals of milky or gray bull quartz that grew inward from the walls of druse cavities to form a comb structure. Vugs are abundant; some are lined with well-formed quartz crystals and/or filled with clay. Some crystals, especially smaller ones weighing less than 250 g, are clear and make electronic grade; most piezoelectric-grade quartz, however, occurs as clear or translucent pyramidal terminations on milky bull quartz crystals that can exceed 1 t.

In Brazil, primary vein deposits in bedrock are overlain by a residual soil blanketing containing alluvial and colluvial deposits of clear, unworn quartz crystals. They also are associated with nearby alluvial placer deposits in present or former stream channels that contain rounded and frosted but usable crystal fragments. Some alluvial deposits consist of several beds of quartz gravel separated by lenses of clay. They are commonly enriched in high-quality quartz, because fractured or twinned crystals break down more readily during weathering and stream transportation. Alluvial placer deposits are elliptical with long axes parallel to the strike of the veins, whereas colluvial placers are fan-shaped (Kuzvart 1984).

Silica Pebble

In addition to the quartz pebble facies of sandstone formations, geologic resources that yield silica pebbles for specialty applications include sedimentary chalk and marl beds and fluvial deposits. These are generally much younger than other specialty silica rock resources. They usually range in age from Cretaceous to Holocene. The high-purity silica pebbles may be flint, quartzite, or massive, vein-sourced quartz.

DISTRIBUTION OF MAJOR DEPOSITS

Sandstone, quartzite, vein quartz, and other silica-rich rocks are common and distributed worldwide, but only at few locations does the rock have the physical and chemical properties required for specialty applications.

Sandstone

Canada

The Potsdam (Nepean) Sandstone has been quarried in eastern Ontario and southern Quebec. It is Late Cambrian to Early Ordovician in age, rests unconformably on an eroded Precambrian surface, and ranges in thickness from 20 to 85 m in Frontenac, Leeds, and Lanark counties in eastern Ontario. Where exposed between Kingston, Brockville, Perth, and Smiths Falls in Ontario, this sandstone consists of well-indurated grains of 75 to 850 μm (Guillet and Kriens 1984). At St. Canut north of Montreal, Quebec, the Potsdam (Nepean) is mined and processed and then sold for use in glassmaking and silicon carbide manufacturing.

The Medina Sandstone of Early Silurian age crops out in several counties west of the Niagara Escarpment in Ontario. Medina sandstone varies in color from gray to brown to red and is fine to medium grained. It has been quarried principally for dimension stone, but it also has been used for mill blocks and in ganister mixes for lining cupolas and ladles in the steel industry and as a source of silica for ferrosilicon and glass.

The Winnipeg Formation of Cambro-Ordovician age crops out on three islands and two promontories in Lake Winnipeg, Manitoba. It consists of nearly white, poorly consolidated, well-rounded sandstone and has been mined principally on the southeastern shore of Black Island. After washing and screening, the product was

barged 140 km south to a plant at Selkirk, Manitoba, for further processing (Guillet and Kriens 1984). The silica sand was used for foundry and filter-bed sand and for sandblasting. The plant at Selkirk, on the Red River 40 km north of Winnipeg, has a production capacity of 115,000 tpy. Although sandstone is no longer mined in Manitoba, the Selkirk plant still processes imported silica sand. East of Lake Winnipeg, 1 km southwest of Seymourville, exploration and development of Winnipeg Formation sandstone, which averages 99.6% SiO_2 , is under way.

Grindstones, millstones, and pulp stones have been produced from Carboniferous and Permian-Carboniferous sandstones in New Brunswick, Nova Scotia, and British Columbia.

Egypt

The El-Zaafarana sand in the Wadi El-Dakhi in the Eastern Desert of Egypt supplies silica sand from semi-isolated blocks of 100-m thickness. El-Zaafarana sand has the following average composition: 97.27% to 99.79% SiO_2 ; 0.04% to 0.11% Al_2O_3 ; 0.01% to 0.18% Fe_2O_3 ; 0.0001% to 0.0005% Cr_2O_3 ; 0.06% to 0.12% CaO ; 0.02% to 0.05% Na_2O ; and 0.02% to 0.04% K_2O . The sand is used mostly in glass manufacture, but beneficiation in the form of tabling and magnetic separation has opened new markets for export in Europe.

The Wadi Qena white sand deposit ranges in thickness from 50 to 100 m in the El-Naqus Formation (Ordovician-Silurian). Average chemical analysis is 95.79% SiO_2 , 4.0% Al_2O_3 , and 0.033% Fe_2O_3 . Sinai deposits also are in the El-Naqus at Gebel El-Gunnah. The alumina content is associated with kaolin clay, which is easily washed from the sand and provides a valuable by-product (Ibrahim 2002).

England

One of the principal sources of grindstones, pulpstones, and millstones in England has been the fine-grained Newcastle Stone quarried from Carboniferous sandstone associated with Coal Measures near Newcastle (Bateman 1959). Derbyshire (Peak) and Yorkshire stones also have been quarried for this purpose from the Millstone Grits, which yield some of the best pulpstones in the world.

Germany and Italy

Carboniferous sandstone for grindstones, millstones, and pulpstones has been quarried in Germany and Italy.

New Zealand

At Pebbly Hills, 50 km northeast of Invercargill on South Island, a quartz pebble conglomerate deposit contains more than 200 Mt of high-quality gravel suitable for silicon metal production. The +12-mm gravel averages more than 98.75% SiO_2 (Benbow 1990; Christie et al. 2000).

United States

The Pottsville Group of Lower Pennsylvanian age contains quartz pebble conglomerate facies in sandstones of the Sharon and Olean formations. These formations have been mined in New York, Ohio, Pennsylvania, and Tennessee as sources of ganister for refractory brick and as sources of metallurgical gravel for silicon metal and ferrosilicon production (Murphy and Brown 1985). The Sharon Conglomerate, the lowermost member of the Pottsville Group, varies in thickness from 15 m in the northeastern Ohio counties of Geauga, Portage, and Summit to 70 m in the southern Ohio counties of Pike and Jackson. It is friable, medium- to coarse-grained sandstone with 95% to 99% SiO_2 containing pebbly zones that occur as long, narrow, north-south-trending bands deposited in channels cut into underlying Mississippian rocks. Metallurgical-

grade quartz pebbles also have been mined in Franklin County on the Cumberland Plateau of east-central Tennessee, where the Sewanee Conglomerate Member of the Pennsylvanian Crab Orchard Formation contains 99% SiO_2 .

At Keck Center in Fulton County, New York, white, granular sandstone containing as much as 99% SiO_2 was mined years ago for use in ferrosilicon production. Sandstone from the Homewood Formation has been quarried for ganister near Upper Hillville and Foxburg, Pennsylvania. Cambrian sandstone has been quarried in Pennsylvania for whetstone manufacture near Allentown in Lehigh County; for ganister and millstone production in Lancaster County; and for ganister in Montgomery County. Fine-grained quartzites and quartzitic sandstones of the Pennsylvanian Stanley and Jackfork formations in the Ouachita Mountains of Oklahoma are suitable for fabricating millstones and buhrstones. In Montana, a sandstone quarry at Columbus in Stillwater County has produced grindstones, and another at Dillon in Beaverhead County has produced metallurgical fluxstone and refractory ganister. High-quality sandstone suitable for specialty applications has been quarried near Denison in Spokane County, Washington.

The Shawangunk Conglomerate outcrops occur in a belt that extends from near Kingston, New York, southwestward into New Jersey and Pennsylvania. It has been quarried extensively for millstones at Shawangunk Mountain and near Kyserike, St. Josen, Granite, and Kerhonkson in New York. It is light gray, well-cemented and hard, pebbly sandstone that ranges in thickness from 15 to 90 m. Tough, fine-grained sandstone near Rawlins in Carbon County and on Baldwin Creek near Lander in Fremont County, Wyoming, was once used for grindstones, as was the Dakota Sandstone northeast of Edgemont, Nebraska, near the South Dakota border. More recently, Dakota Sandstone has been mined in Colorado for use as ganister in refractory applications.

Pulpstones have been fabricated from sandstone quarried in Pierce, Wilkerson, and Skagit counties, Washington, and whetstones have been produced from a 2.5-m-thick bed of sandstone in Skamania County, Washington, between White Salmon and Stevenson. Good pulpstones, grindstones, and millstones also have been produced from the Dunkard and Berea sandstones in Michigan, Ohio, and West Virginia. Hard sandstone, such as the Hindostan Stone from Indiana and the Queen Creek Stone from Ohio, has been used as waterstones (Bateman 1959). Until 1989, sandstone quarried at Orleans in Orange County, Indiana, was fabricated into cuticle removers, sharpening stones, and table coasters.

One of the few remaining U.S. producers of sandstone for nonconstruction purposes is Cleveland Quarries, which extracts and saws the Berea Sandstone into refractory bricks and blocks at South Amherst in Lorain County, Ohio. In this part of northern Ohio, the Berea, which is part of the Waverly Series of Mississippian age, can exceed 68 m in thickness, although it is only 15 m thick elsewhere. Cleveland Quarries cuts Buckeye Silica Stone into beams measuring 1.6 to 3.2 cm^2 in cross-section and into slabs, which are normally 1.2 cm thick. These refractory firestone shapes are used in fabricating acid tanks, steel pickling tanks, acid wash trays, soaking pits, and ladle linings, and for related applications in the steel and chemical industries. The company also has produced grindstones, pulpstones, and deburring media as coproducts at its dimension stone operations.

Quartzite

Australia

In Western Australia, high-purity quartzite is quarried at 60,000 tpy at Picton Junction near Moora, 185 km north of Perth. It is hauled 350 km to a 34,000-tpy-capacity silicon metal plant at Kemerton,

Table 1. Typical composition of Precambrian quartzites in Ontario, Canada

Chemical	Bar River Formation		Lorrain Formation McGregor Point, %	Grenville Quartzite Alban, %
	Badgeley Island, %	Shequiandah, %		
SiO ₂	98.50	97.90	94.10	96.90
Al ₂ O ₃	0.80	0.80	3.46	0.68
Fe ₂ O ₃	0.04	0.08	0.02	0.22
MgO	0.03	0.07	0.13	0.03
CaO	0.00	0.04	0.01	0.00
Na ₂ O	0.01	0.10	0.13	0.01
K ₂ O	0.14	0.30	0.38	0.09
LOI	0.16	0.24	0.43	0.12
TiO ₂	0.02	0.05	0.06	0.06
P ₂ O ₅	0.01	0.03	0.01	0.01
MnO	0.00	0.01	0.00	0.00
Total	99.71	99.62	98.73	98.12

Source: Guillet and Kriens 1984.

20 km north of the port of Bunbury and 165 km south of Perth. The quarry has a capacity of 75,000 tpy, and the Kemerton plant produces about 26,000 tpy of chemical-grade silicon metal.

Canada

In eastern Canada, three quartzite formations constitute the top of the Cobalt Group of Middle to Late Precambrian (Middle Huronian) age. The purest is the Bar River Formation at the top of the series, which is underlain by the Gordon Lake Formation and then the Lorrain Formation. The Bar River high-purity quartzite is white, dense, and massive. It is composed of fine to medium, rounded, and well-sorted quartz grains cemented by secondary quartz (Guillet and Kriens 1984). It is at least 900 m thick and is exposed on a chain of islands in the North Channel of Georgian Bay (Lake Huron), including Pine Island north of Killarney, Ontario, and Badgeley, Centre, Partridge, and Heywood islands.

The Bar River Formation has been quarried at Shequiandah on Manitoulin Island south of Little Current, where lump quartzite was produced for ferrosilicon manufacturing. It is now being quarried on Badgeley Island, 6 km west of Killarney, where the beds dip nearly vertically and contain a few lenses of diabase and amphibolite. Crushed quartzite is shipped to ferrosilicon and silicon metal producers at Welland, Thorold, and Niagara Falls, Ontario; at Bécancour, Quebec; and at Niagara Falls, New York. Fine sand is shipped 190 km south to a plant at Midland, Ontario, for further processing. Production capacity is 1 Mtpy at Badgeley Island and 0.5 Mtpy at Midland. The chemical compositions of the Bar River Formation and Lorrain Formation quartzites in Table 1 illustrate their purities.

The Lorrain Formation approaches the purity of the Bar River Formation, but it contains more alumina. It is exposed along the northern shore of Lake Huron between Sault Ste. Marie and Killarney, Ontario. The Belle vue Quarry north of Sault Ste. Marie formerly supplied quartzite as ganister for refractory brick, and a quarry at Killarney produced lump quartzite for ferrosilicon. Some lump quartzite from the Bar River Formation has been shipped to the Sudbury Area in Ontario and the Noranda Area in Quebec for metallurgical fluxstone in smelting nickel and copper matte. The Lawson Quarry at Whitefish Falls, Ontario, was a captive operation that supplied silica fluxstone to nickel smelters at Sudbury (Guillet

and Kriens 1984). Quartzite also is supplied to a nickel smelter at Thompson, Manitoba.

A friable orthoquartzite of Grenville (Precambrian) age is quarried near St. Donat, Quebec. It is processed at St. Canut, Quebec, 80 km to the southeast, where the Potsdam (Nepean) Sandstone also is quarried. Several quartzite mines in Beauharnois County, Quebec, supply metallurgical-grade stone to local ferrosilicon manufacturers. Elsewhere in eastern Canada high-purity quartzite is found near Labrador City, Labrador. In Newfoundland, 100,000 tpy of quartzite have been quarried at Villa Marie on the Avalon Peninsula in Placentia Bay and shipped to Long Harbour for fluxstone for the electric furnace production of elemental phosphorus. In Nova Scotia, a fine-grained, brittle quartzite of George River (Precambrian) age has been quarried in Cape Breton County as ganister for the refractory brick linings of open-hearth steel furnaces at Sydney. The stone is highly fractured and contains serpentine and chlorite impurities.

In western Canada the Mount Wilson Formation of Ordovician age consists of white, massive, uniform, medium-grained orthoquartzite or silica-cemented quartz arenite. It ranges in thickness from more than 330 m near Golden, British Columbia, to as little as 20 m at Canal Flats, which is 110 km to the southeast. It is quarried at Nicholson, 11 km from Golden in southeastern British Columbia, from which 30,000 to 60,000 tpy are shipped as metallurgical lump for silicon metal and ferrosilicon production at Rock Island near Wenatchee, Washington. It has supplied lump for the manufacture of polycrystalline silicon at Moses Lake, Washington. The Mount Wilson quartzite grade is as high as 99.85% to 99.9% SiO₂ with only 0.10% Al₂O₃ and 0.04% Fe₂O₃ (Simandl, Jakobsen, and Fischl 1992). Reserves of lump silica at Nicholson are estimated at 3 Mt. At Mount Moberly, British Columbia, a friable variety of Mount Wilson quartzite is mined and used in conventional markets for industrial silica sand. It contains 99.67% SiO₂, 0.06% Al₂O₃, and 0.02% Fe₂O₃ (Simandl, Jakobsen, and Fischl 1992).

In the vicinity of Longworth, east of Prince George, British Columbia, the Nonda Quartzite of Silurian-age outcrops extend for a strike length of 2.5 km and may be as much as 250 m thick. It is reportedly even purer than the Mount Wilson stone at Golden (Hamilton and Hora 1987). Quartzite for ferrosilicon and silicon

carbide manufacture formerly was quarried near Oliver in south-central British Columbia near the U.S. border.

Czech Republic

In central Europe, quartzites of Early Tertiary age, especially freshwater quartzites, are used as ganister for refractories and in the manufacture of ferrosilicon and silicon metal (Kuzvart 1984). Since depletion of deposits in the Most District, acid refractories (*dinas*) in the Czech Republic have been made with fine-grained quartzite from the Lahost-Jeníkov deposit near Teplice in North Bohemia. This deposit is 20 m thick, and the stone contains less than 1% Al_2O_3 and more than 97% SiO_2 (Hruska 1991).

Italy

Lump quartzite has been produced at Valsinni in Matera for local steel and chemical markets (Robbins 1986).

Norway

At Tana in northern Norway, quartzite is quarried and used in manufacturing 50% ferrosilicon. Lump quartzite from Tana has been shipped to Iceland for use in a ferrosilicon plant near Reykjavik.

Pakistan

Lump quartzite for use as a steel mill flux has been produced in the Lasbela region of Baluchistan (Griffiths 1987a).

Republic of South Africa

South Africa produces lump quartzite at Donkerhoek, 20 km east of Pretoria, and uses the stone as blast furnace flux for steel mills at Vanderbijlpark and Newcastle. The stone contains more than 95% SiO_2 and less than 0.18% alkalis and 1.7% Al_2O_3 . At Delmas, 85 km from Johannesburg, quartzite is produced for use by domestic ferroalloys and refractories manufacturers. The –180+100, –100+76, and –20+12 mm grades average 98.8% SiO_2 , 0.5% Fe_2O_3 , and less than 0.5% Al_2O_3 , 0.04% S, and 0.01% P, respectively. Metallurgical-grade silica also is produced at Letaba, Bronkhorstspuit, and Lydenburg (Griffiths 1989).

Sweden

At Åmal in Dalsland, high-purity quartzite is quarried and used in ferrosilicon production, in the manufacture of monolithic refractories (Clarke 1987; Russell 1990), and in the manufacture of silicon metal.

United States

In the eastern United States, massive quartzite of the Lower Cambrian Erwin Formation is more than 100 m thick and is well exposed in an anticline in the Lick Mountain District, which is part of the Appalachian Valley in Virginia. It contains 97.63% to 99.37% SiO_2 and has been quarried as metallurgical-grade stone for silicon metal and ferrosilicon manufacture in Virginia (e.g., at Sand Mountain), West Virginia, and east-central Tennessee.

Belts of high-purity quartzite extend across central and southeastern Pennsylvania and across Calhoun, Talladega, Cherokee, Clay, and Cleburne counties in Alabama. Quartzite (actually quartzitic sandstone) from the Lower Silurian Tuscarora (Medina) Formation has been mined in Carbon, Bedford, Blair, and Huntingdon counties, Pennsylvania, for use as ganister in refractory bricks for furnace linings. It also has been quarried in Virginia and near Minnehaha Springs in Pocahontas County, West Virginia, for use as metallurgical stone. It is light gray to white and 120 to 180 m thick in central Pennsylvania (e.g., at Lock Mountain near Point View). In addition to the Tuscarora, quartzite from the Chickies Formation

in southeastern Pennsylvania has been used as refractory ganister and for tube-mill linings. In Cherokee County, Alabama, quartzite containing 97.75% to 98% SiO_2 can be obtained from the Lower Cambrian Weisner Formation.

In Cherokee County, North Carolina, the Tusquitee Quartzite is metallurgical quality. The hard, tough, Poughquag Quartzite near Highland, New York, is suitable for chemical use, for metallurgical stone, and for cutting into blocks for lining grinding mills. Buxton stone has been quarried from the Cambrian Cheshire Quartzite between Dalton and Washington in Berkshire County, Massachusetts, where the formation is nearly 55 m thick at Coltsville. The Carboniferous Quabbin Quartzite is a pure, white, sucrosic but locally flaggy rock that forms part of the Quabbin and Felton mountains in Rhode Island and Massachusetts. Many years ago near Stafford, Connecticut, it was quarried and sawed into hearthstone and firestone for iron ore smelting.

In the central United States, one of the most important sources of specialty silica stone is the Sioux Quartzite, also known as the Sioux Falls Granite, of Late Huronian (Middle Precambrian) age. A fine-grained quartzite that ranges in thickness from 460 to 1,220 m, the Sioux crops out in a belt more than 95 km wide that extends more than 15,540 km^2 from the junction of the Cottonwood and Minnesota rivers at Redstone, Minnesota, westward to Mitchell on the James River in South Dakota. This belt includes parts of the southwestern Minnesota counties of Nicollet, Pipestone, Cottonwood, Rock, and Watonwan; part of northwestern Iowa; and parts of the southeastern South Dakota counties of Turner, McCook, Hanson, and Minnehaha. Outcrops in southeastern South Dakota are most prevalent in river valleys such as those of the Big Sioux at Dell Rapids and South Falls, the Vermillion at Parker, the James south of Mitchell, Wolf Creek at Salem, and Pierre Creek at Alexandria. The color of Sioux Quartzite ranges from pink to orange, purple, and blue; its silica content varies from 96% to nearly 99%; its compressive strength ranges from 1.52×10^5 to 4.96×10^5 kPa; and crushed pieces vary from equidimensional to slabby. The stone's softening point commonly exceeds 1,800°C, and its density is about 1,682 kg/m^3 .

One of the most productive portions of the Sioux Quartzite outcrop belt extends from Jasper in the southwest corner of Minnesota westward to Sioux Falls, Spencer, and Mitchell in South Dakota. Within this district, several companies quarry and crush quartzite for construction applications; one also ships metallurgical-grade material to a ferrosilicon producer in Iowa. The Jasper Stone Co. in Jasper, Minnesota, produces dimension stone for several markets. It also produces some quartzite memorials or monuments, but its chief products are split and sawed blocks for lining tube-type grinding mills, acid tanks, and chutes. As a by-product of its dimension stone operations, Jasper Stone produces quartzite cubes that measure 1.0, 1.2, or 1.6 cm on a side. These are pretumbled for use as grinding media in pebble or ball mills.

Artificially rounded grinding pebbles have also been produced from the Sioux Quartzite near Sioux Falls, South Dakota. Other producing sites in Minnesota are Pipestone, Luveme, and New Ulm, but stone from those locations is sold mostly for use in construction. Some blocks for lining tube mills and chunks as grinding media have been produced by New Ulm Quartzite Quarries, Inc., in Nicollet County, Minnesota. This company also has sold crushed Sioux Quartzite as ganister for steel furnace refractories, for filtration rock, and for fluxstone used in copper smelters. The rock is excellent for the manufacture of refractory silica brick.

Other important resources of specialty silica stone in the central United States are the Baraboo Quartzite in Sauk and Columbia counties, Wisconsin, and the Nesnard Quartzite in Michigan, both

of which are Precambrian (Huronian) in age. The Baraboo Quartzite District is 45 km long, 3 to 19 km wide, and encompasses nearly 583 km². The formation is about 1,220 m thick and consists of massive beds of hard, very tough quartzite comprised of round quartz grains cemented by secondary quartz. Where free of thin slate or schist partings along bedding planes, the stone has a compressive strength of nearly 5.0×10^5 kPa. Until it ceased operations in 1988, Baraboo Quartzite Co. quarried stone from the Netzebaum Quarry near Devil's Lake, Wisconsin, marketing crushed, sized, and pre-tumbled deburring and burnishing media to foundries and metal stamping plants worldwide. Grinding media and liner blocks for pebble mills and ganister for refractory applications also have been produced from the Baraboo Quartzite. In north-central Wisconsin, the Rib Hill and Powers Bluff formations are medium-grained quartzites that contain 99.07% SiO₂ and are suitable for specialty applications.

High-purity quartzite is widespread in the western United States, especially in eastern Washington. The Addy Quartzite of Cambrian age crops out over 648 km² in Stevens County, Washington (Murphy and Brown 1985), and most exposures are within 20 km of a railroad. Until 1991, Northwest Alloys, Inc., a subsidiary of Aluminum Company of America (Alcoa), produced 22,000 tpy of Addy Quartzite from the Blue Creek mine in Stevens County and used the output in the production of silicon metal and ferrosilicon at its plant in Addy, Washington, where ferrosilicon capacity was 27,500 tpy. Elsewhere in Stevens County at Valley Lane Mountain Silica Co. mines part of the Addy Quartzite that is complexly faulted and consists of alternating hard and soft, friable zones. Products contain <0.005% Fe₂O₃. Addy Quartzite also has been quarried at Kettle Falls in Stevens County. Ferry, Pend Oreille, Spokane, and Whitman counties in Washington have either produced or have the potential to produce quartzite for specialty markets.

The Eureka Quartzite of Middle Ordovician age crops out over more than 260,000 km² from Idaho into Southern California (Murphy and Brown 1985). It ranges up to 99.9% SiO₂ and has been mined in Clark County, Nevada, for refractory, metallurgical, and other uses. Quartzite was produced at the Canyon Creek Quarry near Maiden Rock in Beaverhead County, Montana, for use as fluxstone at an elemental phosphorus and ferrophosphorus plant in Silver Bow County, west of Butte, Montana (Rice, Lawson, and Berg 1989).

Quartzite for silicon metal production has been quarried at Rogue River near Gold Hill in Jackson County, Oregon. It also has been produced from the Precambrian Dripping Spring Formation at Oracle, Arizona. Quartzite from the Tintic Formation has been mined in Tooele County, Utah, primarily for the manufacture of refractory coke oven shapes. Quartzite for furnace-lining refractories also has been produced west of Douglas, Arizona. The Sawatch Quartzite of Late Cambrian age is a gray-white, hard, massive formation that lies on an eroded Precambrian surface. It is as much as 40 m thick in the Mosquito Range of Colorado and may be suitable for specialty markets.

Metallurgical-grade quartzite from other sources in the U.S. Northwest has been used in the production of elemental phosphorus and ferrophosphorus at electric furnace facilities. Examples in Idaho include stone quarried in Caribou County for a plant at Soda Springs and the Kit Creek mines in Bannock County, which supply plants at Pocatello.

Novaculite

United States

The Arkansas Novaculite Formation outcrops occur in several narrow belts that extend along the borders of the Benton–Broken Bow

Uplift portion of the Ouachita Mountains between Little Rock, Arkansas, and Atoka in southeastern Oklahoma. This portion of the Ouachita Fold Belt ranges from 25 to 65 km in width and extends east–west for 320 to 360 km. Mining operations that produce novaculite for commercial uses such as oilstones, hones, files, and whetstones, and for other specialties, are concentrated in Garland County just northeast of Hot Springs, Arkansas. A few deposits also are mined in nearby Pike and Montgomery counties, Arkansas. In 2005, the Arkansas Geologic Commission listed 10 companies as novaculite producers in this area. Nearly all commercial whetstone mines are confined to the massive lower member of the formation.

In Oklahoma, the outcrop belts of novaculite continue from the Potato Hills east of Tahlequah through Latimer, Pushmataha, and McCurtain counties and westward to near Atoka in Atoka County. Silica rock that has been called novaculite is part of the Caballos Formation in Brewster County, southwestern Texas. It is intensely folded and fractured but crops out prominently and extensively in the Marathon Uplift Area (Jaster 1957). In the counties of Alexander and Union in southern Illinois, widespread deposits of primary novaculite and alluvial novaculite gravel are present in the same area where major deposits of tripoli are mined. A novaculite locality near Marquette, Michigan, also had been reported (Jaster 1957); deposits outside the United States however, have not been well documented.

Vein Quartz

Angola

Production of lascaras from the Pocarica vein deposits near Conda in Cuanza Sul Province was nationalized in 1979 with the establishment of Miniquartzo to manage operations. In 1975, Angolan exports of lascaras had reached a level of 3,900 t; in 1980, exports ceased. One cultured quartz producer at Libramont, Belgium, used to purchase nutrient quartz from Angola but switched to Namibian lascaras in 1989.

Brazil

Brazil has the largest known reserves of natural, piezoelectric-grade quartz crystal and lascaras in the world, with the total estimated at 26.8 Mt (Smith 1984b). On the Brazilian altiplano, an extensive plateau underlain by Precambrian and Lower Paleozoic rocks, there are hundreds of small, deeply weathered vein and alluvial deposits scattered over thousands of square kilometers, and are a twice the size of Texas (Bates 1960). This area is located along the southeastern margin of the Brazilian Shield. Production comes mostly from the states of Minas Gerais, Santa Catarina, São Paulo, and Bahia, although significant reserves also are known in Espírito Santo, Paraíba, Paraná, Rio de Janeiro, and Rio Grande do Sul. The richest deposits are in Minas Gerais.

Some piezoelectric-grade crystal is produced in Brazil, but shipments from the official export cities of Rio de Janeiro, Bahia, and San Salvador consist predominantly of lascaras for growing cultured quartz crystals and for the manufacture of fused quartz preforms after extensive chemical refinement in Europe. Of the total quantity of quartz produced in Brazil, approximately 97% is lump for industrial applications such as silicon metal and silicon alloys manufacture, and the remaining 3% consists of piezoelectric crystal, lascaras, and decorative specimens. Quartz for silicon metal smelting is produced at Gouveia in Minas Gerais.

Canada

The Mount Rose deposit of high-purity, lascar-grade vein quartz is located near Armstrong, British Columbia. The Fs quartz vein,

situated 40 km northeast of Kamloops, British Columbia, has supplied milky quartz for silicon carbide manufacture in Oregon. The vein deposit is at least 400 m long and 3.5 to 15 m wide. Near Oliver in southern British Columbia, quartz veins that are 0.3 to 4 m wide cut the Oliver Plutonic Complex of Late Jurassic age. They are widest in the porphyritic quartz monzonite phase of the complex and have been quarried for fluxstone and ferrosilicon manufacture. The Gypo deposit near Oliver reportedly produces less than 10 ktpy of lump quartz (Simandl, Jakobsen, and Fischl 1992). The White Rock quartz, kaolin, and mica deposit 45 km northwest of Shelburne, Nova Scotia, contains residual quartz from leucocratic granite, which underwent hydrothermal alteration. Current plans are to produce ground silica as a replacement for white marble chip and sand (*Industrial Minerals* 2001).

Chile

Lump quartz is produced from vein deposits for use as fluxstone at copper smelters. The largest producer has capacity for 200,000 tpy, but the +0.635-cm stone is not of exceptional chemical purity. A pegmatite deposit containing electronic- and possibly optical-grade quartz also has been found in Chile.

Egypt

Quartz vein deposits occur in Egypt at 38 locations in the Eastern Desert. The ycut across basic and ultrabasic metavolcanics. The deposits of Abu-Marwa (20 Mt) and Gebel Delhami I and II (60 and 10 Mt, respectively) contain very-high-grade quartz that averages 99.02% to 99.98% SiO₂, 0.40% to 0.26% Al₂O₃, and 0.15% to 0.18% Fe₂O₃. There is potential for production of high-quality silica products such as fused silica. Egypt currently exports quartz in 1- to 25-cm lumps or sub-100 mesh powder (Ibrihim 2002).

Greece

In eastern Macedonia, metallurgical-grade lump quartz has been mined from vertical pegmatite veins 1 to 8 m wide in schist host rock at Paranesti, Thessaloniki. The quartz contains 99.5% SiO₂, 0.04% Al₂O₃, 0.03% Fe₂O₃, and 0.01% each of CaO, K₂O, and Na₂O. Most has been exported to silicon metal manufacturers (Griffiths 1985a; Clarke 1987; Georgiades 1988).

Guyana

Quartz crystal of possible optical and electronic quality is associated with diamonds in alluvial deposits in Guyana.

India

India produces lump quartz containing 99.8% SiO₂ for domestic metallurgical uses and for export, which is used predominantly in the manufacture of fused quartzware for the electronics industry. There are more than 100 vein quartz mines in India, 40 of which produced >1,000 tpy. One producer exported 21,800 t of high-purity quartz in 1990 (Russell 1991). Andhra Pradesh led in production, followed by Karnataka, Rajasthan, Gujarat, Tamil Nadu, Haryana, and Madhya Pradesh (Smith 1984a). The Indian Bureau of Mines reported 128 quartz mines producing 279,385 t in 2003–2004 (Indian Bureau of Mines 2004).

A large pegmatite deposit was discovered in the 1990s at the village of Uchapalli in the state of Andhra Pradesh. Current quartz crystal (3,000 tpm) and silica sand (10,000 tpm) serve markets for ceramics and other applications (*Industrial Minerals* 2004).

Italy

Lump quartz has been produced at Montioni, Sanfront, Martiniana Po, and Sondalo, Italy, for the following markets: ferrosilicon, sili-

con metal, refractories, filtration, abrasives, chemicals, and blast furnace steelmaking (Robbins 1986). One company has produced lump quartz at Sondalo in Lombardy for silicon metal manufacture, and the majority is ground into potter's flint for the ceramics industry (Clarke 1987).

Malagasy

The chief source of lumps in Malagasy is vein and associated alluvial placer deposits in the northeastern coastal and central plateau regions.

Namibia

In Namibia quartz for the electronics industry has been recovered as a by-product of lithium ore production at the Rubicon mine near Karibib. Another large quartz deposit is located at Marbad near Windhoek (Murray 1989).

Portugal

Quartz crystal and lump quartz have been mined at three sites in Guardia, Portugal, for sale to silicon metal and ferrosilicon manufacturers (Clarke 1987).

Republic of South Africa

A dike of massive, high-purity quartz in Precambrian host rocks near Pietersburg in the northern Transvaal region of South Africa is known as the Witkop deposit and is quarried by Samancor Ltd. The open-pit mine, located 380 km north of Johannesburg, supplies –38 +25 mm lump to a silicon metal smelter nearby (Griffiths 1989).

Spain

About 20 industrial silica producers in Spain have a capacity of 3.3 Mtpy, and about 70% of this capacity is controlled by two companies: Belian-owned SCR-Sibelo SA and Arenas Siliceas SA (ASSA). Nine other companies are each responsible for about 7% of silica production. The majority of the smaller companies produce silica as a by-product of feldspar and kaolin production. The glass and foundry industries consume most of the silica production. Additional markets include abrasives, hydraulic fracturing, chemicals industry, filtration, and others (Sims 1998).

Cuarzos Industriales SA mines a vein of quartz or quartzite at Vivero and exports most of its annual output to silicon metal and ferrosilicon producers in France, Germany, Norway, and Sweden (Griffiths 1985b).

Sri Lanka

Veins of massive high-purity quartz (>99.8% SiO₂) have been found at more than 50 locations in the areas of Openaika, Pelmadulla, Pusella, Rattota, and Ratnapura in Sri Lanka (Harben 1991). The deposit at Galaha (Ambalamana) contains inferred reserves of 6 Mt (Herath 1990).

Venezuela

Quartz crystal for growing cultured quartz and for the manufacture of silicon metal and silicon alloys is produced at Santa Elena, Bolivar.

United States

Hydrothermal quartz veins in sandstone and shale are the most common sources of electronic-grade quartz crystals and lumps around the world. In the United States, minor quartz crystal deposits have been found in California, Idaho, Oklahoma, and Virginia, but major deposits are near Hot Springs, Arkansas, in the foothills of the Ouachita Mountains. Arkansas deposits are mined mostly for

quartz crystal specimens, not for electronic-grade crystal. World-renowned crystals with the exceptionally smooth, clean faces are extracted from veins and cavities in sandstone at two small open pits in Garland County. The best-quality, water-clear specimens having highly polished faces are found in cavities filled with reddish brown, sticky, rouge-like clay.

The only producer of lascas in the United States is Coleman Quartz, Inc. This company mines one of two massive bull quartz veins that lie mostly conformably between units of thinly bedded and deeply weathered shale at an open pit near Paron, Arkansas, 48 km northeast of Hot Springs in Saline County. Veins range from 2.4 to 3.7 m in width and extend for 0.4 km in strike length. Annual production varies from 450 to 570 t. The entire deposit has not been drilled yet, but resources are estimated at 200,000 t. Mine-run material is hauled by trucks to the company processing plant 48 km away. The quality of finished lascas produced in Arkansas is equal to or slightly superior to that of lascas produced in Brazil, and it is usually less variable. Total impurity levels range from 25 ppm for grades #1 (90% clear) and #2 (50% to 60% clear) to 44 ppm for grade #3 (translucent) and 54 ppm for grade #4 (opaque). Impurities include 15 to 20 ppm Al; 2 to 25 ppm Na; 2 to 10 ppm K; 2 to 5 ppm Fe; and 1 ppm each of Ca, Mg, Li, and Ti (Griffiths 1987b). The relatively high sodium level is associated with bubble fluid inclusions.

In Connecticut, between the towns of Ledyard and North Stonington, the massive Lantern Hill vein quartz deposit was mined for its quartz crystal. The vein measures 2,000 m long and 300 m wide and yields products that grade 99.0% to 99.4% SiO₂. A similar deposit is located just north of Glasgow about 16 km north of Lantern Hill. Vein quartz and high-purity quartzite deposits were once mined in Adams County, Pennsylvania, and at Port Henry and Fort Ann, New York. Bull quartz dikes have been found west of Wirtz in Franklin County, Virginia, and numerous vein quartz deposits are known in the North Carolina counties of Anson, Moore, Montgomery, Harnett, Buncombe, and Transylvania. In Texas, massive quartz veins occur in Precambrian rocks of the Llano Uplift and in the Carrizo Mountains of Culberson and Hudspeth counties.

High-purity, metallurgical-grade silica resources are abundant in the western United States, particularly the Pacific Northwest. Silicon metal and ferrosilicon plants at Rock Island, Washington, and Springfield, Oregon, now use mostly quartzite, but in the past they were supplied with lump quartz from massive vein deposits at the following locations: (1) north of Weiser, Idaho; (2) at Basin and west of Galen, Montana; and (3) near Hawthorne, Nevada. The deposit near Weiser is a quartz plug within granodiorite and yielded material averaging 99.78% SiO₂. The Basin deposit is a quartz plug within quartz monzonite and yielded metallurgical lumps grading with more than 99.5% SiO₂. Near Galen, a massive quartz body averaging 99.82% SiO₂ is present within Precambrian limestone and quartzite on the southwestern slope of the Flint Creek Range. The vein near Hawthorne, Nevada, measures nearly 850 m long and 95 m wide, is associated with Jurassic granite, and yielded stone that averaged 99.89% SiO₂ (Peterson 1976). Similar deposits in western Montana are located at Deer Lodge, Haines Point, and Quartz Creek.

The Quartz Mountain deposit in Spokane County, Washington, is a large vein of massive quartz within granitic host rock. It has been quarried as a source of lump quartz for silicon metal and ferrosilicon producers. Other deposits in eastern Washington include (1) the Latshaw deposit, a 200-m² plug of quartz 20 km north of Spokane with 98% SiO₂, which has been mined mostly for ganister; and (2) massive quartz veins at Mount Spokane and near

Mica Peak. In central Washington, a dike of white quartz, 15 m wide and averaging 96.6% SiO₂, is found near Wenatchee and another large vein is located near Merritt in Chelan County. In western Washington, three large quartz veins are located near Marblemount in Skagit County, and another has been mined at Rockport, 13 km to the southwest. Other deposits of massive quartz have been quarried for ganister in King and Pierce counties. Altogether, there are 36 known massive quartz deposits in 13 counties in Washington, most of which are found as veins and pods in metamorphic rocks or as the cores of pegmatites.

Elsewhere in the western United States, a pure quartz dike 300 m long and 60 m wide has been mined in Jackson County, Oregon. Lenses of massive quartz or quartzite more than 60 m thick are found in metamorphic rocks of Paleozoic age 30 km northeast of Oro Grande and 15 km east of Victorville in San Bernardino County, California. They have been quarried mostly for ganister. The Veta Grande mine near Carson City, Nevada, is another massive vein deposit that has yielded metallurgical-grade lump quartz.

Other Countries

Chamber-type pegmatites that contain quartz crystals are of Precambrian age in Brazil, Malagasy, and Ukraine, but they are of Late Paleozoic age in central Kazakhstan, China, Mongolia, the northern Ural Mountains, and the Plateau Central in France. Hydrothermal quartz veins that yield piezoelectric crystals in the Urals are found in Proterozoic mica schists and lower Ordovician quartzites. Inclusion-free quartz from hydrothermal veins at Detkovice in the Czech Republic contains 99.43% SiO₂ and 0.07% Fe₂O₃ after hand sorting. Similar deposits at Graupa, Czech Republic, contain 99.86% SiO₂ and 0.062% Fe₂O₃ after hand sorting and only 0.003% Fe₂O₃ after further washing, calcination, magnetic separation, and chemical refining (Kuzvart 1984). Elluvial placer deposits of quartz crystals in the Ural Mountains of Ukraine may contain gold in economically recoverable amounts.

Other producers of high-purity lump quartz for silicon metal and silicon alloys manufacture as well as specialty glass and refractory products are Finland, France, and former Yugoslavia. Silicon and ferrosilicon producers in Japan use quartz imported from China, Korea, and India. Elluvial placer deposits of quartz crystals containing no gold or diamond coproducts have been found in China. Other vein deposits of quartz crystal or lascas are known in Uganda, South Africa, and Australia. High-purity quartz in pegmatites was discovered recently in Cordoba Province in Argentina.

Silica Pebble

Canada

A large deposit of well-rounded quartzite pebbles is found near Cypress Hills, Alberta. As grinding media, pebbles from this deposit compare favorably with flint pebbles produced in Denmark (actually Greenland). Lump quartz has been produced from a deposit on the southwestern shore of Lake Baskatong at Charlevoix near St. Ludger, Quebec. The material quarried was used mostly in silicon metal manufacturing and, to a much lesser extent, as grinding pebbles.

Europe

Silex is a term used commercially for flint, chert, or chalcedonic silica that is produced in several European countries, including France, Belgium, England, and former Yugoslavia. Silex is used in the form of round pebbles as grinding mill media and as cut blocks, known as Belgian block, for iron-free grinding-mill linings. Silex from Belgium is an extremely fine-grained, tough, chalcedonic

form of silica containing secondary calcite and radial chalcocite (Griffiths 1987b). Silex from former Yugoslavia is somewhat coarser grained and contains tightly packed quartz crystals. Flint pebbles produced in France, Belgium, England, and Denmark (Greenland) are available in two grades and in 7 to 12 sizes ranging from 1.3×1.6 cm to 13.3×15.2 cm. Some pebbles from Denmark are as much as 20.3 cm in diameter. Pebbles of "Select" quality from Dieppe, France, contain 98.43% SiO_2 , 0.02% Fe_2O_3 , and 0.10% Al_2O_3 .

Blocks of silex, or buhrstone, have been produced in Belgium from deposits just east, north, and west of the town of Mons. Blocks range in thickness from 60 to 160 mm, are rectangular or conical, and are used for lining cylindrical, tube-type pebble and ball mills. The blocks, cut and fabricated by hand, have been recovered from flint nodules in a marl quarry at Eben-Emael. The lowest stratigraphic intervals, at a depth of more than 30 m, have produced the best-quality flint. The average chemical composition is 94.0% SiO_2 , 4.9% $\text{CaO} + \text{CaCO}_3$, 0.9% MgO , and 0.1% Fe_2O_3 . One company in Belgium produced approximately 1,000 tpy of finished blocks (Benbow 1989) and another in Jaen, Spain, produced about 500 tpy (Clarke 1987). Silex blocks and crushed silex also have been produced from flint pebbles mined at Dieppe, France.

Flint nodules as grinding-mill media are produced from Cretaceous chalk formations in western and northern Europe. Perhaps the largest resource is in the Paris Basin, where a 400-m-thick section of chalk contains flint nodules (Kuzvart 1984). Flint pebbles also are produced from chalk deposits as a by-product at cement operations in southeastern England. At Northfleet and Shoreham, Clarke (1984) reported pebble capacity at approximately 1,000 tpy, although output in 1984 was only 500 to 600 tpy. Pebbles are washed to remove chalk and iron oxides for use mostly in ceramics. Three sizes are produced: $-10.16+5.08$, $-5.08+2.54$, and -2.54 cm (Clarke 1984).

United States

One of the most important sources of metallurgical-grade silica gravel for silicon metal and high-purity ferrosilicon production in the eastern United States is the high-level terrace deposits of the Citronelle (Lafayette) Formation of Pliocene or Holocene age. These are fluvial channel and bar deposits found in raised terraces that roughly parallel the present course of the Pee Dee River in North Carolina and of other major rivers in the coastal plain of South Carolina, Georgia, Florida, and Alabama. They consist of unconsolidated sand and gravel that lie unconformably on Late Cretaceous sediments. The most productive area encompasses 65 km² and is centered at Lilesville in Anson County, North Carolina. The Pee Dee terraces near Lilesville contain a well-developed basal gravel zone 1.5 to 6 m thick overlain by sand and a few lenses of gravel and clay. They consist of 46% sand and nearly 54% gravel; the gravel is 75% to 83% quartzite and 17% to 25% vein quartz (Callahan and Craig 1990).

Sand and gravel from Pee Dee River terraces have been mined near Lilesville, North Carolina, for construction sand, metallurgical-grade pebble, and clear or white pebbles exceeding 5 cm for packing acid to be used in the chemicals industry (Callahan and Craig 1990). The pebbles also have been used as grinding-mill media. Dredging on Beech Island in the Savannah River has produced sand and gravel from floodplain deposits near Augusta, Georgia. Metallurgical-grade gravel has been produced from similar deposits in Harnett County, North Carolina.

Lower-purity ferrosilicon (e.g., 50% Si) has been manufactured in the southeastern United States from silica gravels dredged from the Coosa River north of Montgomery, Alabama,

and from the Alabama River between Montgomery and Selma, Alabama. In Florida, subrounded quartz and quartzite pebbles have been dredged from the Escambia, Apalachicola, Flint, and Chattahoochee rivers. Additional river-bed gravel deposits have been produced at Lecanto and Crystal River, Florida. Blocks for lining grinding mills and artificially rounded grinding pebbles were formerly fabricated from silica pebbles recovered from beds of Ocala Limestone in Florida. Quartz and quartzite pebbles in the Bryn Mawr Formation of Pliocene age have been mined for metallurgical and refractory applications in Harford County, Maryland, and to a lesser extent in nearby Baltimore, Carroll, and Howard counties. Grinding pebbles and blocks for lining grinding mills have been produced from residual deposits of chert derived from the Fort Payne Formation near Iron City in Wayne County, Tennessee.

Numerous alluvial deposits containing laterally extensive but thin beds and lenses of flint pebbles occur in interstream divides, river terraces, and major stream valleys in the Gulf of Mexico Coastal Plain of Texas. These deposits extend west from the Guadalupe River to the Rio Grande. Grinding pebbles that can be milled to a quality equal to that of similar pebbles produced in Europe have been mined in Texas from deposits in Frio, Bastrop, Llano, and Travis counties; pebbles in deposits associated with the Colorado and Brazos rivers, however, generally are unsuitable for use as grinding media. Some flint, as stock from which blocks for lining grinding mills are cut, has been produced from the Edwards Formation in western Travis County, Texas. Flint nodules from mining operations in the Austin Chalk Formation in south-central Texas have been recovered for captive use as an abrasive medium in the production of ground silica flour.

Silica pebbles, apparently derived from the Sioux Quartzite, are abundant along the shores of Lake Superior between Grand Portage and Pigeon Point, Minnesota. As grinding-mill media, they compare favorably in performance with flint pebbles produced in Europe. Many years ago, silica pebbles recovered from the beach between Oceanside and Encinitas, California, were used as grinding-mill media. Because they were harder, coarser-grained, and rougher in texture than flint pebbles from Denmark, the silica pebbles were faster cutting when used for grinding hard materials. Round silica gravel used in water filtration has been produced at several locations in the United States, including Muscatine, Iowa; Eau Claire and Fairwater, Wisconsin; and Thompson, Ohio.

TECHNOLOGY Exploration

Exploration for deposits of specialty silica materials is guided by knowing which geologic formations are likely to contain rock of suitable quality. Geologic reconnaissance and mapping are then conducted in areas where these formations are present. At hard-rock prospects of sandstone, quartzite, novaculite, and vein quartz, evaluation normally requires drilling and drill sample testing to establish the extent and amount of reserves. Percussion drilling is seldom adequate because physical properties of the stone are as important as, or even more important than, its chemical purity. Chip samples from percussion drilling provide some indication of chemical purity but are unsuitable for many physical property measurements. Diamond-bit core drilling, therefore, is usually necessary at some stage in the evaluation process. Problems of poor core recovery are common when holes are drilled at angles between horizontal and vertical and especially where the silica rock is highly fractured, jointed, or friable. Where conglomeratic sandstones are sought for their silica gravel content, core drilling must be close spaced to delineate pebble-rich zones.

At prospects where silica gravel is present in unconsolidated sediments, or where host rocks enclosing quartz veins are deeply weathered, drilling can be impractical. In such cases bulldozers or backhoes dig trenches to locate and sample the resource; then samples are washed and screened to determine the yield of product per cubic meter excavated. Exploration of river gravel deposits is done by dredging.

Mining

Deposits of vein quartz in Brazil are small and irregular in shape, and are mined mostly by hand in open pits that are seldom more than 20 m deep. Bulldozers remove overburden, and pumps dewater the pit. Clear, piezoelectric-grade crystals of small size are common, but those that weigh 250 g or more are rare, accounting for only 1/10,000 (0.01%) of the total mass of a vein filling (Kuzvart 1984). The ratio of clear crystal to total material mined ranges from 1:1,000 to 1:1,000,000, so enormous quantities of milky quartz are extracted to recover only a few kilograms of piezoelectric crystal (Lamey 1966). In exceptionally rich pockets, the yield of such crystal can be as much as 0.4% or even 1.6%.

During World War II, 40,000 m³ of vein quartz mined in Arkansas yielded 200 t of rock crystal, but only about 2 t of the crystal were suitable for piezoelectric applications (Kuzvart 1984). In the 1990s, three deposits of vein quartz had been mined for quartz crystal specimens and lascas in Arkansas. At the Paron mine in Saline County, there is little or no overburden, and thus very little drilling and blasting. Massive bull quartz for lascas production has been mined with a backhoe during the summer months, and stockpiles containing about 2,000 t have sustained processing operations for a year. Two crystal specimen operations in Garland County, Arkansas, used similar mining methods as those at Paron; however, the pits at the former are much deeper, no drilling and blasting has been used, and pockets of crystals have been mined by hand. Bull quartz extracted from these pockets has been used as feed for lascas.

Sandstone and quartzite for nonconstruction dimension stone are quarried in a manner that uses joints and bedding planes to advantage. Primary vertical cuts along quarry walls or for separating key blocks can be made with channeling machines, although drilling and broaching is more standard practice. In drilling and broaching, rows of vertical holes 51 mm in diameter are drilled; then the channel cut is made with pneumatic or hydraulic wedging hammers or by detonating very light charges of black powder. Quarry blocks are freed from a bench or ledge by drilling rows of horizontal holes and then either detonating low-velocity explosive charges or using the plug-and-feather method of manual wedging. Blocks are moved from quarries to finishing plants with fixed or mobile derricks, front-end loaders, or trucks. Similar methods are used for quarrying whetstone-grade novaculite in Arkansas, where the yield of usable stone from the total amount quarried, or within a deposit, ranges from a maximum of 10% for hard, translucent grades to a maximum of 25% for softer grades.

Metallurgical-grade quartzite deposits in Oregon and Washington are quarried by conventional drilling and blasting in open pits with benches 12 m high and 6 m wide (Peterson 1976). Similar methods are used in extracting quartzite on Badgeley Island, Ontario (Guillet and Kriens 1984). In Stevens County, Washington, the friable portion of Addy Quartzite has been mined in two open pits with benches as high as 45 m. About 50% of the rock can be ripped by bulldozer, but the rest requires drilling and blasting. Conventional drilling and blasting also is used in open-pit mining of conglomeratic sandstone that contains metallurgical-grade pebbles, such as from the Sharon Formation in Ohio.

Metallurgical-grade quartz gravel from the Alabama River between Selma and Montgomery, Alabama, and at Beech Island, South Carolina, near the Savannah River has been recovered by dredging. Suction dredges are suitable for deposits consisting of loose sand and gravel, whereas bucket-ladder or suction cutterhead dredges are used for deposits that contain beds or lenses of clay. Raised fluvial terrace deposits of metallurgical gravel or pebble, such as those along the Pee Dee River in the Carolinas, have been mined with front-end loaders, draglines, and hydraulic excavators.

Processing

Brazilian lascas is quartz that is defective for piezoelectric (e.g., radio component) or optical applications because it is cloudy or milky instead of clear or contains optical or electrical twinning, cracks, or bubble fluid inclusions. It is produced by hand sorting and trimming such material from higher-quality, electronic-grade quartz crystals.

In Arkansas, mine-run vein quartz is crushed and wet screened to $-3.175 + 1.27$ cm, washed, leached in vats of hot oxalic acid, and then rinsed several times with water. It is then hand sorted, dried, and finally examined on a light table for defects before being packaged in 45.36-kg bags. Defective rejects, -5.08 cm mine-run rock, and the -1.27 cm screenings represent waste that averages about 50% of the rock mined, so 2 t of vein quartz are mined for 1 t of finished lascas sold.

Processing metallurgical-grade quartzite and novaculite consists only of crushing, washing, and screening to sizes ranging from $-10.16 + 3.81$ to $-3.81 + 0.32$ cm. Metallurgical-grade quartz and quartzite gravels from river channel and raised terrace deposits are processed similarly, except that no crushing is required.

Quartzite, sandstone, and jasper slabs for nonconstruction dimension stone historically were split by hand. Because they were rough on all six sides, more mortar was required for their installation. Quarry blocks today are cut with wire saws and are split hydraulically. Acid blocks have either two or four sides sawed smooth with the other sides hydraulically split and rough. They consist of beams and slabs of sandstone that are sawed to a thickness of 10.16 to 20.32 cm. Grinding mill and chute liner blocks usually are sawed on all six sides. Red and gray jasper (quartzite) in Minnesota is still cut, trimmed, and shaped by hand into rectangular adamant silica blocks measuring 5.08 to 12.7 cm thick, 10.16 to 15.24 cm wide, and 20.32 to 25.4 cm long for lining pebble mills. The unevenness or irregularity of the surfaces of these blocks is an advantage because it reduces the need to install lifters in a mill.

To increase the yield of salable product from each quarry block, one producer in Minnesota cuts and shapes cubes of adamant silica by hand for use as grinding media in competition with flint pebbles produced in Europe. Cubes are pretumbled in a mill to round off the edges and reduce high initial wear that results in about 20% weight loss. The smallest cube that can be hand cut economically measures about 5.08 to 6.35 cm on a side, so larger cubes cannot be used as deburring media. Crushed quartzite has been pretumbled near Baraboo, Wisconsin, and sold as a deburring medium in eight sizes ranging from $-19.05 + 14.29$ to $-3.175 + 2.38$ mm.

Grindstones made mostly of sandstone are produced in Europe as blocks that are cut and shaped, measuring 0.6 to 1.5 m across. Pulpstones from the same sandstone beds are cut and shaped into blocks 1.5 m in diameter and 0.9 to 3.0 m wide. The stone is used for grinding logs into paper pulp and often is seasoned for 1 to 2 years after it has been quarried, but before it is cut (Bate-man 1959).

Novaculite oilstone s, files, and whet stones are produced in Arkansas by sawing quarry blocks with diamond-tipped saws and then shaping and lapping the cut stones by hand. The yield from carefully selected quarry blocks ranges from about 10% for hard, translucent grades to 25% for softer grades, and a maximum yield of 30% to 40% for perfect stone, which is rarely found. This means that the overall yield from all novaculite quarried, or within a deposit, ranges from only 1% for translucent grades to 6% or 7% for softer grades. At least one company in the district crushes, screens, and pretumbles waste or scrap novaculite generated at whetstone operations, and markets 11 different sizes from 5.08 to 0.635 cm and finer as deburring media for barrel tumbling and vibratory finishing.

Specifications

Metallurgical Applications

Crushed quartzite and novaculite lumps and round quartz and quartzite pebbles from fluvial deposits and conglomeratic sandstones are used in electric furnace production of silicon metal, ferrosilicon (FeSi), and other silicon alloys. Because vein quartz is more brittle and usually generates excessive fines during handling, most FeSi producers prefer quartzite, even though its Al_2O_3 and Fe_2O_3 content tends to be higher. Also, vein quartz often contains fluid inclusions, which cause it to decrepitate into additional fines when exposed to furnace temperatures. For metallurgical applications, silica rock should be tough (i.e., not friable), should have a high thermal shock resistance, should be free of fines when delivered, and should not crumble or decrepitate into fines when heated.

Fines cannot be tolerated in submerged arc electric furnaces because they reduce the porosity of the charge, which blocks the flow of gases, causes premature fusion and crusting, and results in a gas buildup that produces furnace blowouts. Blowouts are sudden releases of high-temperature gas consisting of CO and SiO, resulting in a loss of silicon and, therefore, reduced efficiency. High-purity novaculite has been used in silicon metal and FeSi production, but it generates fines when heated, creating foam that accumulates in the furnace. Costly downtime is spent periodically cleaning this accumulation of foam.

Silicon metal producers prefer to use quartz or quartzite lumps that exceed 2.54 cm in diameter, have a minimum softening point of 1,700°C, and do not decrepitate below 950°C. Lumps can range from 1.27 to 10.16 or 1.27 cm in average diameter, but -10.16 + 3.81 and -7.62 + 2.54 cm sizes commonly are used most. The rock should contain at least 98.5% or 99% SiO_2 (typically 99.3% to 99.8% SiO_2) and less than 0.1% Fe_2O_3 ; 0.15% Al_2O_3 ; 0.2% CaO; 0.2% MgO; and 0.2% loss on ignition (LOI). LOI is directly proportional to the tendency of a rock to decrepitate on heating. Fe_2O_3 and CaO are especially critical impurities for metallurgical-grade silicon.

Silica feed for chemical-grade silicon production should have high reactivity and very low alumina content. Some grades of silicon metal require feed containing less than 0.05% Fe_2O_3 ; 0.10% Al_2O_3 ; 0.005% CaO; and 0.002% TiO_2 . In all cases the rock should contain essentially no phosphorus, sulfur, or arsenic impurities, which are particularly objectionable because they form poisonous gases in the furnace. Metallurgical-grade quartz from Brazil is typically high in titanium, so silicon metal produced from it is suitable for secondary aluminum refining but not for manufacturing chemicals such as silanes and silanes.

Ferrosilicon producers can accommodate smaller lumps of silica rock ranging in diameter from 0.32 to 10.16 cm, the size varying in direct proportion to the silicon content of the alloy produced.

Table 2. Typical composition of quartz gravel for ferrosilicon manufacture

Gravel Type	Composition, wt %					
	SiO_2	Al_2O_3	Fe_2O_3	CaO	P	Ti
North Carolina terrace gravel	99.2	0.068	0.41	0.031	0.007	0.006
Alabama river gravel	98.7	0.27	0.53	0.039	0.009	0.018

Source: Alsobrook 1994.

The rock should contain more than 96% SiO_2 and preferably more than 98% SiO_2 . It also should contain less than 0.4% Al_2O_3 (usually less than 0.25%) and 0.2% Fe_2O_3 . During smelting, Al_2O_3 influences the consumption of electric energy, which can amount to as much as 40% or 45% of the manufacturing costs. Sulfur content should be very low, although phosphorus can range up to 0.1%. Iron and carbon content usually is not as critical as the amount of alumina, alkali, and alkaline earth metals. One U.S. producer's maximum specifications are 0.03% Fe_2O_3 ; 0.20% Al_2O_3 ; 0.01% CaO; and 0.02% TiO_2 . Silica rock for silicomanganese (75% Si, 25% Mn) does not have to be of such high purity. Typical analyses of quartz gravels used in FeSi production in the southeastern United States are shown in Table 2.

The Alabama river gravel in Table 2 is produced in various sizes, including -15.24 + 2.54 and -7.62 + 2.54 cm. Quartz gravel from North Carolina is produced in sizes ranging from +5.08 to -0.635 + 0.3175 cm.

In furnaces used to produce silicon carbide, a bed of -10.16 + 2.54 cm silica rock, through which gas is drawn, filtered, and cleaned, is placed on the floor. Although angular rock has more surface area, round river rock is preferred because it compacts into a looser, more permeable bed.

In smelting iron, nickel, zinc, lead, and copper ores, the price of a acid flux is more important than its chemical purity, so local sources of -4.445 + 1.905 cm stone are normally used. The charges to blast furnaces and basic open-hearth furnaces used in steelmaking are trimmed with washed -1.59 + 0.635 or -2.54 + 0.79 cm river gravel that contains >99% SiO_2 and is usually locally available and inexpensive.

The electric furnace production of elemental phosphorus uses -2.54 + 0.3125 cm lump quartz or -3.175 + 0.635 cm quartz pebble from river channel deposits. In general, quartz or quartzite used as fluxstone in metal and phosphorus smelting should contain >90% SiO_2 and <1.5% Al_2O_3 , 1.5% Fe_2O_3 , and 0.2% combined CaO and MgO.

Abrasive Applications

Quartzite, flint, jasper, and novaculite for use as abrasive media in grinding mills and deburring equipment must have high crushing strength, high specific gravity, toughness or durability, high purity, homogeneity, high hardness, and resistance to staining, fracturing, chipping, and high temperatures. The rock should have low porosity and must contain no toxic substances or dark-colored metallic impurities such as iron and manganese. It must be tightly cemented and chemically inert in the presence of strong alkalis and acids. The media should be round and closely sized. It also should produce a white powder when abraded. The size and shape of constituent grains and their cleavage and fracture characteristics are also important.

High-density grinding media are preferred because their greater impact and grinding force mean that less mill volume is

needed for a given load of media, or that a faster grind can be obtained without reducing the media load. In either case, production capacity is greater than with less-dense media. Novaculite is not usually suitable as a grinding medium because of its comparatively low specific gravity, friability, and low resistance to breaking on impact during milling. Crushed quartzite usually does not qualify for high-impact applications because crushing can produce microfractures in the rock that cause it to break apart during use. Properties that determine the suitability of silica rock for use as a grinding medium also determine its suitability as grinding mill lining.

Silica rock that qualifies as a grinding-mill medium and lining material is also normally suitable as a deburring abrasive, where closely controlled sizing is required to minimize lodging. Certification tests are carried out in a 0.28-m³ tub-type vibrator that is loaded with 90.7 kg of media and 4.5 kg of angle iron and is operated at 1,800 vibrations per minute for 24 hours. A steady, uniform rate of cutting and wear is desired for the development of a fine, high-luster finish on the deburred part. Performance of the abrasive medium is evaluated in terms of its cutting rate, wear rate, cutting efficiency, and the quality of finish produced on the metal part, which should be free of scratches. The cutting rate is the weight percent of metal removed, the wear rate or chipping factor is the weight percent of media lost as nonrecyclable fines, and the cutting efficiency factor is the ratio of cutting rate to wear rate, with high values preferred.

Very few types of sandstone qualify for use as grindstones, which require uniform hardness and sharp, even grains. The rock must be cemented tightly enough to be sound and tough, but not so tightly cemented that it glazes during use. Coarser grains grind faster but produce a rougher surface. Pulpstone also requires that the cement be weak enough to wear and permit the harder quartz grains to protrude. Coarse-grained sandstone produces wood fiber that can be too coarse (Bateman 1959).

Electronics

Quartz crystals for use in electronics and optics should weigh no less than 50 to 100 g (Kuzvart 1984). Piezoelectric-grade crystals should contain at least 16.4 cm³ of flawless material (Lamey 1966). Even clear crystal is unfit if it is optically or electrically twinned or if it contains phantoms, cracks, liquid bubble inclusions, rutile fibers, or intergrowths with other minerals. Phantoms are growth outlines within a crystal that are commonly marked by very fine clay particles (Bates 1960).

Pieces of quartz crystal that weigh 10 to 30 g and defective material trimmed from piezoelectric-grade crystals can be used as the nutrient in growing cultured (synthetic) quartz crystals if their iron and aluminum content is low enough. Crystal growers prefer to use a nutrient (i.e., lascalas) that contains <50 ppm total impurities, although material containing 50 to 100 ppm impurities can be used where requirements are less critical. Iron and aluminum are the most important contaminants because they govern the amount of undesirable sodium and lithium that enters the crystal during the growth process.

Nonpiezoelectric-grade pieces of ultrapure quartz that weigh 10 to 30 g also can be fused and fabricated into optical fiber preforms (e.g., rods and tubing); precision optical and electro-optical blanks, billets, and prisms; specialty lamp tubing; and quartzware apparatus (e.g., crucibles) for semiconductor electronics and laboratory applications (Kuzvart 1984). Manufacturing transparent fused quartz (vitreous silica or quartz glass) products requires a feed that contains less than 30 ppm (0.003%) total impurities; this means a silica content of at least 99.997%. The minimum silica purity required in manufacturing opaque fused quartz glass is 99.8% (Griffiths 1987b).

Acid Tanks and Towers

Blocks of sandstone and quartzite for lining acid tanks, towers, and trays are resistant to hydrochloric and sulfuric acids, but not to hydrofluoric or high-temperature phosphoric acids. Blocks should have good abrasion resistance, a crushing strength of 55×10^3 to 70×10^3 kPa, and a transverse strength of 8.3×10^3 to 9.0×10^3 kPa. Quartz and quartzite gravel used as a packing medium in acid towers must have low porosity (e.g., less than 3%), high crushing strength, high degree of size uniformity, and high surface area per cubic meter. Gravel should be resistant to dissolution by sulfuric acid and should have a neutral or slightly acid pH; a pH of 7.5 or higher can cause problems. Low porosity is required for low acid absorption, and a high crushing strength minimizes the generation of fines that can plug gas orifices and other equipment at the base of a tower. The packed bed of gravel should contain a large percentage of void space per cubic meter.

Air Preheaters

High-purity quartz river gravel is used in three of the four layers that serve as a heat-transfer medium in the chambers of air preheaters. Gravel that is 12 to 15 mm in diameter is used for the bottom (first) layer, accounting for 5% of the weight of the bed. Gravel that is 3 to 5 mm in diameter is used for the second and topmost (fourth) layers, accounting for about 70% of the weight of the bed. Gravel must contain at least 99% SiO₂; it should be round so that the bed has sufficient void volume to allow adequate heat transfer and pressure drop. Angular fragments restrict air flow. Gravel also should have high thermal conductivity, high heat storage capacity, and high thermal efficiency (e.g., 98%) and be closely sized.

Filtration

Rapid gravity filters at municipal water treatment plants contain quartz gravel 2.54 cm in diameter at the base, grading upward to 3.2 mm at the top, for a total bed thickness of 30.5 to 45.7 cm. According to American Water Works Association Standard B100-01 (AWWA 2001) specifications, only uncrushed media can be approved for municipal filtration installations. The media should contain <25% flat or elongate fragments having length:width ratios of 5:1 or more. Crushed rock is angular, so it tends to interlock, as do elongate fragments, in a filter bed. When the bed is backwashed periodically to flush out entrained sediment, media fragments that are locked together will erupt. Round quartz gravel does not interlock and provides the 35% to 40% void space required in a filtration bed. Although gravel need not be of high chemical purity, it should have high specific gravity, tolerance of acid and alkaline source waters, chemical inertness, good mechanical strength to maintain particle shape during loading and compaction, high coefficient of uniformity of size, and an effective size that meets filter specifications.

Trickle filter installations use silica rock that is $-11.43 + 3.81$ cm as the support medium on which bacteria are grown for digesting raw sewage sludge. The rock should be of high chemical purity (e.g., >98% SiO₂), but not necessarily high density. It should be angular so that it has high surface area. Filter beds used in drying sewage sludge for compost applications require silica gravel with a high coefficient of size uniformity and a particle size of between 3.2 and 12.7 mm. Gravel that is $+15.9$ mm in diameter is used in septic leach fields.

Refractories and Other Uses

Quartzite (ganister), quartz gravel, and vein quartz used in manufacturing refractory products usually are crushed to between -3.81 cm

and -2.38 mm and must be low in iron, alkali, and phosphorus impurities. The stone must have low porosity after being fired at $1,500^{\circ}\text{C}$. Fine-grained quartzites usually have lower porosity than coarse-grained quartzites after firing. Even more stringent chemical specifications apply to novaculite used in producing special vitreous silica refractory materials. The best quality novaculite for this purpose, from Arkansas, contains 99.19% SiO_2 ; 0.02% to 0.03% Fe_2O_3 ; 0.10% to 0.25% Al_2O_3 ; and 0.043% $\text{Na}_2\text{O} + \text{K}_2\text{O}$ and is crushed to $-3.81 + 1.27$ cm.

For use as aggregate in furan polymer concrete, where it is loaded at 90 wt %, silica rock must be angular but can range from $44\text{ }\mu\text{m}$ to 6.35 mm.

USES

Electrometallurgy

Specialty silica gravel and lump metallurgical-quality quartz are used in the production of silicon metal and silicon alloys and as a flux in the smelting of elemental phosphorus, iron, nickel, zinc, copper, and lead.

Depending largely on the purity of the silica feed, silicon metal is produced in electronic grades for semiconductor markets, in chemical grades for manufacturing silicones and silanes, and in metallurgical grades for secondary aluminum refining. Consumption of quartz raw material ranges from 2.6 to 3.5 t per finished ton of 96.0% to 99.7% Si metal.

Although FeSi is produced in at least six different grades ranging from 20% to 95% Si, standard grades are 50% Si (typically 48%) and 75% Si (typically 76%). In addition to silica rock, the charge to an electric furnace consists of coal, coke, or charcoal as the reductant, wood chips to provide porosity, and steel scrap or iron ore as the source of iron. Consumption of quartz raw material per finished ton of alloy ranges from 1.05 to 1.1 t for 45% to 50% FeSi, from 1.7 to 2.0 t for 75% FeSi, and from 2.3 to 2.5 t for 90% FeSi.

Steelmaking consists of electric furnaces that remelt scrap, blast furnaces that reduce iron ore pellets to pig iron, and basic oxygen furnaces (BOFs) that convert iron into steel. The principal use of silica rock in steelmaking is as an acid flux and slag conditioner at blast furnace operations. Its functions are (1) to correct, balance, or otherwise adjust the basicity ratio ($\text{CaO}:\text{SiO}_2$) of the burden when too much lime has been charged; (2) to raise the volume of slag sufficiently to ensure complete removal of sulfur and alkalis; and (3) occasionally to clean the furnace. Electric arc furnace mini-mills are operated with a basic, not acid, furnace environment, so they use lime or dolomitic lime and fluorspar instead of silica as fluxes. In remelting scrap, they do use alloys such as 75% FeSi and silicomanganese (SiMn). For more complete discussions on fluxes in steelmaking, the reader is referred to the chapters on metallurgical fluxes in this volume.

Elemental phosphorus is still produced in the United States in Idaho. It is manufactured by first nodularizing beneficiated phosphate sand in rotary kilns, then smelting the nodules to elemental phosphorus in electric furnaces charged with fine coke and quartz pebbles.

Abrasives

Novaculite from Arkansas and silex from Belgium are cut into whetstones, oilstones, hones, files, and other special shapes for residential, industrial, leisure, and craft uses. Residential uses include sharpening kitchen knives and other cutlery such as scissors, shears, and lawn and garden tools. Industrial uses include sharpening and honing cutting surfaces; and polishing metal surfaces in watch and clock manufacture and repair, in gun and reciprocating jet engine manufacture and repair, and in tool and die work. Leisure

applications include sharpening sports knives, arrowheads, fishhooks, and spear points. Craft applications include gun engraving, jewelry making, sharpening woodcarving tools, and other engraving (Austin 1991). Hard Arkansas whetstones are used for fine finishing and edging work, whereas Ouachita Stone whetstones are used in coarse sharpening of large tools such as scythes.

Price lists from Arkansas novaculite producers usually contain four grades, about a dozen shapes, and hundreds of different sizes of cut stone products. Grades are Soft Arkansas for medium work, Hard Select Arkansas for fine work, and True Hard Arkansas and Translucent for extra-fine work. The most popular grade is Soft Arkansas, which is used by woodcarvers, sportsmen, butchers, commercial knife sharpeners, and homemakers. The Translucent grade is used mostly for obtaining an extremely fine polish on industrial and surgical instruments. Shapes include bench stones; triangular and square files; special round, flat, bevel, diamond, and oval files; slip stones; carving tools; pocket stones; penknife pieces; and hones.

Oilstones for fine sharpening have been made from fine-grained sandstone quarried in Ohio. Waste from whetstone operations in Arkansas is used as an abrasive medium in wet (vapor) pressure blasting; as a grinding and deburring medium; as a $74\text{-}\mu\text{m}$ loose-grain abrasive for cleaning printing press plates; and in the manufacture of cuticle stone. A large U.S. producer of cuticle and coaster stones in Bedford, Indiana, has used a patented process that uses epoxy resins to bond scrap novaculite, which have been ground to 149 and $74\text{ }\mu\text{m}$.

Pretumbled novaculite of non-whetstone-grade and hand-cut quartzite cubes are used in barrel tumbling and vibratory machines for light burr, rust, and scale removal, radius formation, cleaning, and degreasing. Applications include the refining, burnishing, and high-luster finishing of cast and punched parts made of mild steel, hardened steel, yellow brass, aluminum, and stainless steel. Additional applications include deflashing, degating, and deburring of cast and extruded polytetrafluoroethylene (PTFE) rings and other plastic parts. Rough, untumbled, and unrounded media are seldom used.

The deburring market is highly diverse and fragmented, ranging from numerous small tool and die shops to huge metal casting foundries and stamping operations in the automotive and aerospace industries. The U.S. abrasive media market consists predominantly (+99%) of wet (versus dry) deburring operations. A typical 0.57-m^3 vibratory machine uses a 907-kg load of abrasive media and requires nearly 23 kg per day of new media, so the daily makeup represents an average 2.5% of the media load. Novaculite is not suitable for use with complicated, intricate castings where abraded particles can lodge in blind holes and tight spots, but it can be used with lighter-weight, simpler castings.

Quartzite (jasper) quarried in Minnesota and silex (chalcedonic silica) produced in France are cut and shaped mechanically by hand into rectangular blocks that are used in lining tube or cylindrical, tile-type ball and pebble mills. Grouted into place with high-alumina cement or epoxy resin loaded with alumina or silica, jasper linings seem to last indefinitely in mills used for grinding pyrophyllite, feldspar, high-purity quartz, industrial silica flour, talc, gypsum, clays, and wollastonite, for example. They are used primarily where iron contamination from metal alloy liners or alumina contamination from ceramic liners cannot be tolerated. The same quartzite is cut into cubes that are prerounded and used as the grinding medium in cylindrical or conical ball and pebble mills. Flint pebbles and silex (buhstone) cubes from Texas, France, Belgium, England, and the former Yugoslavia also are employed for this purpose.

Natural silica grinding media have been replaced to a large extent by high-density, high-alumina manufactured ceramic media.

They are still used for some nonmetallic minerals and ores, as mentioned earlier, as well as for some metallic ores. They are preferred for fine grinding materials that are sensitive to contamination by discoloration, such as specialty coatings (paints), certain chemicals, ceramic glazes and enamels, or organic pigments, white Portland cement clinker, and technical ceramic raw materials (e.g., zircon). A major use for silica media is in grinding porcelain glazes and lacquers, because their use does not cause the product to become cloudy during grinding.

Although largely replaced now by synthetic abrasives, grindstones made from fine-grained sandstone are still used for sharpening edge tools such as saws, machine knives, scythes, shears, and other harvesting and die-making equipment. Hard sandstone, quartzite, and quartz pebble conglomerate have been used as millstones, which are large circular stones that include buhrstone and chaser stone. True buhrstone is chalcedonic silica, and is used in grinding grain, paints, fertilizers, and graphite. Chaser stone has been used for grinding feldspar, quartz, barite, and other nonmetallic minerals (Bateman 1959). Sandstone also is cut into pulpstones for grinding logs into pulp for paper manufacture.

Acid Tanks and Towers

At South Amherst, Ohio, sandstone (firestone) is quarried and cut into blocks or bricks used at steel mills for lining soaking pits, acid tanks, acid wash trays, and steel pickling tanks. The blocks also are used at chemical plants and foundries, by oil-field service companies, and to line acid towers. Acid blocks cut from quartzite at Jasper, Minnesota, are used mostly in the chemical industry.

Acid towers usually are packed with ceramic media of various sizes and shapes, but can be packed with quartz or quartzite gravel. There are hundreds of applications for such towers, including the drying (dehydration) and purification of gases such as chlorine at chemical processing plants. Sulfuric acid or another acid is introduced at the top of a tower containing a packed bed of gravel, and it coats the surfaces of the packing as it trickles downward. Wet chlorine gas is then introduced at the bottom of the tower, and as it migrates upward through the packing, its water content is stripped by the gravel's acid coating.

Refractories

Sandstone, quartzite, quartz pebbles, conglomerate, and non-whetstone-grade novaculite are crushed and used as gneiss in manufacturing refractory bricks, tiles, kiln furniture, and other shapes as well as ramming mixes, mortars, patching compounds, and other monolithic specialties. Such products are used in lining cupolas, ladles, Bessemer converters, metal-pouring shrouds and nozzles, crucibles, mixer cars, by-product coke oven doors, and blast furnace hot stoves and checkers at steel mills. They are used also in lining kilns for firing ceramic products and in the glass industry for lining glass tank crowns and regenerator checkers. High-purity, non-whetstone-grade novaculite also can be fused in high-temperature rotary kilns to manufacture refractories. These water-quenched chunks of vitreous silica are crushed, closely sized, and sold as shell and core sand to investment casting foundries. Vitreous silica has an extremely low coefficient of thermal expansion and good dimensional stability at high temperatures.

Electronics and Optics

Natural electronic-grade quartz crystal was the principal form of quartz used in electronics and optics until 1971, when cultured (synthetic) quartz crystal first predominated. Cultured crystal has now displaced natural crystal in nearly all applications.

Lascas mining and processing in Arkansas ceased in 1997. No firms reported the production of cultured quartz crystal in the United States in 2004. Capacity for cultured quartz crystal production in the United States still exists, and it relies entirely on imported and stockpiled lascas for feed material. It requires between 1.3 and 1.4 kg of lascas to produce 1 kg of as-grown cultured quartz. Cultured quartz crystal production has increased steadily over the past several years, especially in Asia (Dolley 2005).

The worldwide consumption of further purified, lascas-grade quartz in the manufacture of specialty lamp tubing, fiber-optic preforms, precision optical and electro-optical devices, and fused quartzware for electronics (e.g., semiconductor) and laboratory markets is easily 10 times the consumption of lascas in the cultured quartz industry. In the manufacture of vitreous silica or fused quartz products, the ratio of quartz feed to finished product ranges from 1:1 to 3:1. Most of the production of fused quartz is consumed in-house by manufacturers for applications such as laboratory ware in the manufacture of semiconductors and quartz tubes and rods as the raw material for fiber optics (O'Driscoll 1997).

Other Uses

Air preheaters operate continuously at 1,165°C to 1,294°C and are used in the thermal destruction of volatile organic compounds (VOCs) present in offgases from industrial facilities such as painting booths. Their heat-transfer chambers are equipped with perforated plates at the bottom, above which are placed four layers of heat-transfer media. The bottom (first) layer consists of coarse quartz gravel, the second and top (fourth) layers consist of finer quartz, and the third layer, where the heating elements are installed, consists of synthetic mullite aggregate. Altogether, the four layers constitute a bed averaging approximately 30 t of media in each preheater.

Applications for specialty silica stone in water filtration range from rapid sand or rapid gravity filters to trickle filters and drying beds. The former is used to purify municipal water supplies, and the latter is used to filter municipal sewage sludge used as compost at mushroom farms and for other agricultural purposes. Water filtration applications also include commercial and industrial water treatment installations and septic leach fields. The second and fourth quarters usually are the annual peaks for filter media sales. Another filtration application of quartz gravel is for cleaning gases during silicon carbide manufacture, where it is placed as a lining on the floor of electric furnaces.

Other commercial applications for specialty silica rock, often produced as a by-product, include the following construction products: roofing granules and chips; decorative, exposed, semi-light-weight aggregate in precast concrete panels and other white architectural concrete products; aggregate in polymer concrete used to protect concrete flooring from acids; aggregate bonded with epoxy resins to manufacture curtain walls; aggregate for sub-base road construction; nonpolishing, skid-resistant aggregate for asphalt highways; riprap and railroad ballast; and nonskid aggregate in the top coating of concrete flooring subjected to heavy wear such as from forklift traffic.

Non-whetstone-grade novaculite is ground and used as an industrial filler or extender in latex paints, silicone rubber, and plastic casting, molding, and potting compounds (frits and glazes), such as for large electrical insulators.

Miscellaneous uses include poultry, pigeon, and parakeet grit (mixed with crushed oyster shells); sandblasting sand; decorative landscaping and garden stone; sodium silicate manufacture; the polishing of electronic microcircuit dice pedestals; aquarium

chips; aggregate for swimming pool plaster; and fine aggregate in abrasion-resistant linings.

ECONOMIC FACTORS

Production

According to the USGS (Dolley 2003), no vaculite from Arkansas accounted for most of the value and quantity of specialty silica stone sold or used by U.S. producers in 2003. The Arkansas Geological Commission (1999) listed 10 companies that produce whetstone and oilstone in Arkansas. The USGS reported seven producers of specialty silica stone in Arkansas (Dolley 2003). The whetstone and oilstone industry in Arkansas includes integrated companies that quarry crude no vaculite and cut finished products, companies that cut finished shapes from purchased crude stone, and companies that quarry and sell crude no vaculite or that produce pretumbled deburring media from purchased scrap. The USGS last reported the production of crude silica stone (in Ohio) for grindstones in 1998 (Bolen 1998). Finished specialty silica stone products sold or used by U.S. producers in 2003 amounted to 513,000 t valued at \$3.63 million, including grindstones, oilstones, and whetstones (Dolley 2003). U.S. production of industrial silica gravel for electrometallurgical, filtration, and other specialty applications in 2003 amounted to 1.14 Mt valued at \$15.3 million (Dolley 2003). Table 3 summarizes U.S. production statistics for several forms of specialty silica materials for 1999 to 2003. Similar statistics for other countries are seldom published.

In 1997 mining and processing of quartz lascas ceased in the United States (in Arkansas), and no U.S. firms reported the production of cultured quartz crystals in 2004. Cultured quartz crystal production capacity still exists in the United States using imported and stockpiled lascas as feed material. In the past several years, cultured quartz crystal was increasingly produced primarily in Asia. Electronic applications accounted for most industrial uses of quartz crystal; other uses included special optical applications (Dolley 2005).

In the United States, production statistics for cultured quartz crystals were withheld to avoid disclosing company proprietary data. Trade data for cultured quartz crystal and devices with mounted quartz crystal are available, but lascas import data are not available. Exports of cultured quartz crystals (excluding mounted quartz crystals) totaled about 92 t, and imports (excluding mounted quartz crystals) totaled about 3 t in 2004. The United States is 100% import reliant. Brazil, Germany, and Madagascar are reportedly the major sources for lascas, and Canada is becoming an increasingly important supplier. Other possible sources of lascas are China, South Africa, and Venezuela (Dolley 2005).

U.S. production of industrial silica gravel for silicon metal and ferrosilicon manufacture in 2003 amounted to 594,000 t valued at \$8.49 million (Dolley 2003). Data for silica gravel used in filtration and nonmetallurgical flux applications were withheld in 2003 to avoid disclosing company proprietary information. The USGS reported that silica gravel production under the category "Other uses, specified" amounted to 541,000 t valued at \$6.8 million (Dolley 2003). Similar statistics for other countries are seldom published.

Silica stone for which U.S. production statistics are unavailable are (1) Arkansas novaculite used in manufacturing silicon metal and alloys, vitreous silica refractories, oil-field proppants, deburring media, and fillers; (2) quartzite quarried in Minnesota and South Dakota for ferrosilicon production, grinding mill pebbles and liners, and fluxstone; (3) high-purity quartz mined from pegmatite and vein deposits in South Dakota and New Mexico for the manufacture of specialty glass products; (4) sandstone quarried in

Pricing

Table 4 shows the average unit values of specialty silica materials produced in the United States from 1999 to 2003. The values shown are heavily skewed toward whetstone-grade novaculite and do not represent all specialty silica materials as defined in this chapter.

Lascas production in Arkansas ceased in 1997. At that time, the USGS reported that the average value for lascas was \$1.20/kg (Bolen 1998). The USGS estimated the average value of as-grown cultured quartz to be about \$81/kg in 2003. Similarly, the USGS

estimated the average value of lumbered quartz, which is as-grown quartz that has been processed by sawing and grinding, to be about \$176/kg in 2003. The U.S. Department of Commerce (DOC), which is the major government source of U.S. trade data, does not provide specific import or export statistics on lascas. Some lascas was imported from Brazil in 2003, according to some consumers (Dolley 2003). In previous years, the U.S. Census Bureau provided data on quartz crystal export and import quantities and values; that data included zirconia, however, which inadvertently was reported to be quartz crystal not including mounted piezoelectric crystals.

Table 4 summarizes prices for silica gravel produced in the United States. Prices reported for silica gravel produced in silicon metal and ferrosilicon manufacture ranged from \$4.53/t in the Midwest to \$14.82/t in the South. Silica gravel used in the filtration market ranged from \$33.14/t in the West to \$51.43/t in the Northeast. The average price range for silica gravel in nonmetallurgical applications had a range of \$9.99/t in the West to \$16.53/t in the Midwest. The largest discrepancy in average price per ton of silica gravel was reported for the "Other uses, specified" category from \$10.41 in the Midwest to \$51.43 in the Northeast (Dolley 2003). The cost of transportation generally doubles the free on board (f.o.b.) prices quoted by silica producers. Prices are slightly higher for larger sizes (e.g., $-10.16 + 3.81$ and $-7.62 + 2.54$ cm) than for smaller sizes (e.g., $-3.81 + 1.27$ and $-3.81 + 0.95$ cm). Silicon metal and 75% FeSi manufacture require higher purity and larger sizes, whereas less pure and smaller stone (e.g., inexpensive river gravel) can be used in producing 50% FeSi, silicomanganese (SiMn), ferrochromium silicon, and magnesium ferrosilicon. Blast furnace operations in the steel industry do not require high-purity silica rock as an acid flux, so they normally trim with river gravel that is dredged or mined locally and delivered at competitive prices. Nonferrous metal smelters (e.g., elemental phosphorus smelters) likewise are extremely sensitive to raw material pricing and do not require high-purity fluxstone.

The value of crude Arkansas novaculite depends on its suitability for cutting it into finished whetstones and related products. Generally, Washita grade is less expensive than Black Hard Arkansas grade. Industrial files and special shapes are priced higher than sporting goods products.

In 2003, silica stone product exports from the United States had a value of about \$7.8 million. Exports were categorized as "hand sharpening or polishing stones" by DOC and accounted for most of the silica stone products exported in 2003. The value of imported silica stone products was \$6.3 million in 2003. These imports were hand sharpening or polishing stones, which accounted for most of or all the imported silica stone products in 2003. A portion of the finished products that were imported may have been made from crude novaculite produced in the United States and exported for processing (Dolley 2003).

Rounded flint pebbles from France, Belgium, England, and Denmark are available in as many as 12 sizes for use as grinding media in pebble mills. In the United States, they are priced according to the size the customer orders; small orders generally are more costly than bulk quantities. Also, the smallest pebbles command the highest prices because they are scarce; but they provide the fastest grind. Pricing also depends on whether the pebbles are of Standard or Select quality; the most popular pebble is Standard #1, which is $-6.35 + 3.81$ cm in size.

Cut and pretumbled cubes of jasper (quartzite) from Minnesota are now rarely used as grinding media in pebble mills. Cut blocks of Minnesota jasper for ball and pebble mill linings are priced higher if purchased through distributors rather than directly from the producer. Before the operation closed in 1988, pretumbled

chunks of quartzite from a producer in Wisconsin were sold as deburring media. Prices varied not by the size of stone but also by the size of the order, namely, less than 1,815 kg, between 1,815 and 9,075 kg, and more than 9,075 kg.

Round river gravel for use in water filtration is packed in 22.68-kg, 45.36-kg, and 1-t bags and shipped in lots ranging from 36 to 36,000 t. Prices of filter gravel vary with the stone size and whether it is sold direct to municipal waterworks, to contractors who install water treatment plants, or to manufacturers of filter plants. In the United States, round, high-purity quartz gravel for use in air preheaters also is priced similarly and packaged in 1,360-kg bags.

Transportation

The place value of specialty silica materials varies inversely with their market value. High-priced products such as whetstone-grade novaculite, lascas, fusing-grade lump quartz, flint grinding pebbles, silex and quartzite grinding-mill linings, electronic-grade quartz crystal, and some metallurgical-grade lump quartz and quartzite are items of international trade. Some quartz gravel for water filtration also is exported. Lower-priced materials such as are used in refractories, as fluxstone at ferrous and nonferrous metal smelters, and in the manufacture of some silicon alloys are shipped only to local or regional markets.

Silica raw materials of metallurgical-grade for silicon metal and alloys production used to be obtained within 500 km of the smelter. Rising power costs have forced many electric furnace operations to relocate closer to supplies of low-cost energy, and rising transportation costs have forced others to relocate closer to steel mills. In both cases, silica rock now is hauled from more distant sources (Murphy and Brown 1985). Centers of ferroalloy production in Canada are located where hydroelectric power is available and comparatively inexpensive, for example, in British Columbia; near Welland, Thorold, and Niagara Falls, Ontario; and near Beauharnois, Quebec. Major centers of ferroalloy production in the United States are also where hydroelectric power is available, such as in the Tennessee Valley Authority service territory (i.e., Alabama, Kentucky, Ohio, Tennessee, and West Virginia), the Niagara Falls, New York, area, and the Pacific Northwest (Washington and Oregon).

Some U.S. manufacturers of silicon metal and alloys purchase (1) quartz gravel from North Carolina delivered in open-top, gondola-type railcars holding payloads averaging 68 t (Peterson 1976); (2) crushed Sioux quartzite delivered by rail or river barge from South Dakota; or (3) high-purity novaculite delivered by low-cost river barge in 1,360-t payloads from Arkansas. Other manufacturers, particularly those with operations located close to their silica source, prefer to receive just-in-time shipments by truck to minimize inventory costs. In any case, electric power costs generally represent at least 33% of the total direct operating cost for silicon metal production, whereas silica raw materials account for about 11% and 8% of the direct operating costs for ferrosilicon and silicon metal manufacturing, respectively. Lump quartz from Spain is used in producing 75% FeSi and silicon metal in Norway, where half its delivered price includes transportation.

Alternative Materials

Grinding-Mill Linings

Pink granite from Salisbury and Faith, North Carolina, was once used in lining pebble mills, but it has been replaced by Minnesota jasper (quartzite), which is harder and tougher and can be shaped more accurately. Blocks of Minnesota jasper still are used for lining tile mills at feldspar grinding operations. Hardinge mills for

grinding table and wheelstonite are lined occasionally with the lightest, BB grade of silex (buhrstone) blocks measuring 25.4 to 27.94 cm long, 10.16 cm wide, and 10.16 to 12.7 cm thick. Silex blocks from France and Belgium are not readily available and are very expensive, so they are seldom used today.

Most ball and pebble mills are lined with ceramic materials, chromium-molybdenum steel alloys, aluminum alloys, fused alumina, or special rubber. Where an iron-free lining is required, natural stone has been replaced largely by 5.08-cm-thick, single-piece porcelain ceramic liners that contain 27% to 74% Al_2O_3 . Ceramic liners also are constructed with precast porcelain blocks set with special cements or epoxy resins. They are used in grinding paint, ceramic, and chemical materials.

Grinding-Mill Media

Manufactured abrasive media, including carbon steel and chrome alloy steel balls, glass beads, high-alumina porcelain balls, and zirconia beads, have widely replaced flint pebbles, silex, and jasper chunks and cubes in ball and pebble mills. High density, high-alumina, porcelain grinding media are manufactured as balls, discs, cylinders, and rods ranging from 1.59 mm to 7.62 cm in diameter with alumina content from 87% to 99%. They are made in various grades of hardness, which averages about 8 on the Mohs scale, and they have a specific gravity of 3.4, which is 40% to 50% of forged steel. Their bulk density averages about 2,210 kg/m^3 , compared to 1,680 kg/m^3 for Minnesota jasper.

The prices of high-alumina ceramic grinding media depend on their size, shape, and Al_2O_3 content; small diameter sizes are more expensive than large diameter sizes. Smaller sizes are used for really fine grinding, for example, for inks, paints, and chemicals.

Factors in choosing grinding abrasives include the price of the media, grinding speed, media wear or loss, product contamination, and mill lining wear. In most applications, high-alumina ceramic materials are the most cost-effective, explaining why they have captured most of the grinding media market. Their high specific gravity ensures high grinding speed, and their toughness minimizes fracturing, wear, and loss. Although their high density can cause strain on mill bearings, they are longer lasting than Belgian silex pebbles, and their use usually extends the life of grinding-mill linings. Feldspar producers typically experience a media loss of only 0.55 kg per ton of ground feldspar. Some ground silica flour producers use pretumbled jasper (quartzite) cubes or flint pebbles in combination with high-density porcelain ceramic balls as a blended medium to reduce costs and the load on mill bearings.

Forged steel and stainless-steel balls from 1.27 to 15.24 cm in diameter often are used where iron contamination of the product is of no concern. Zirconia grinding media have a high specific gravity and possess wear resistance similar to ceramic materials. Glass beads range in specific gravity from 2.5 for lead-free glass to 2.94 for leaded glass. They vary in diameter from <1 to 1.5 mm. Chunks of recycled high-silica refractory brick have been used as a grinding medium, but they cause excessive wear to the mill lining at the discharge end. In some instances the grinding medium (e.g., nepheline syenite) has been fabricated from the same rock as that being ground.

Deburring Media

As in the case of grinding mill media, natural stone abrasives once used as deburring media have been displaced largely by manufactured products, including glass beads, fused aluminum oxide, high-alumina ceramic materials, stainless steel, and even plastics. Such media are used in vibratory and tumbling machines for the deburring and surface finishing of stamped metal parts and foundry castings, and for deflashing cast plastic parts.

High-alumina ceramic and fused or sintered aluminum oxide tumbling media are manufactured in a variety of shapes, called preforms, including cones, tubes, pyramids, and stars. They are harder, tougher, and more abrasive than natural stone media and do not present a silica hazard. They also are produced in crushed and rounded form, called random shapes or nuggets. Their bulk density ranges from a low of 1,360 kg/m^3 for ceramic media to a high of 2,080 to 2,400 kg/m^3 for fused aluminum oxide. Pricing depends on the size of medium, its Al_2O_3 content, and the quantity ordered. Small sizes are priced 7.5% to 8.5% higher than large sizes. The higher the Al_2O_3 content, the faster the cutting ability and, therefore, the higher its price; so the highest priced media are small, complex preforms having very high alumina content. Preforms having the highest Al_2O_3 content cut fastest, but they have the lowest efficiency because of a high rate of wear. They are used in applications where an extra-fast cutting rate is more important than media loss and composition.

Ceramic media may be too aggressive in some applications and not aggressive enough in others. Polyester plastic preforms, which are less aggressive, average 1,040 kg/m^3 in bulk density. Prices for stainless-steel deburring media tend to be higher than those for ceramic media. Emery and corundum also have been used as random-shaped, natural abrasive deburring media.

Acid Tanks and Towers

Extruded bricks can be used instead of silica pebble as a lining for acid towers. Bricks are composed of coarse, -0.84-mm silica sand plus ball clay or an organic binder. Special ceramic, plastic, or metal materials can be used instead of quartz gravel as the packing medium for such towers. Plastic media are least expensive, but they are not wetted easily by acids and can be used only with low operating temperatures. Where operating temperatures are high, ceramic and special metal packing media are used. Ceramic materials are wetted more easily by acids and are less expensive than metallic media.

Air Preheaters

Instead of high-purity quartz gravel, most manufacturers of air preheaters use high-alumina ceramic particles to fill the metal chambers. Ceramic media are heated to high temperatures and serve as heat exchangers in stripping VOCs from industrial exhaust gases that are blown through the chambers.

Silicon Metal

At East Selkirk, Manitoba, silicon metal is smelted from silica sand instead of conventional metallurgical-grade quartzite. Silica sand is imported from the United States and is smelted in a plasma furnace to produce silicon metal for the manufacture of silicone fluids, resins, and elastomers.

Cultured Quartz

As the seed for growing synthetic quartz crystals, plates cut from specially grown cultured seed crystals have nearly replaced those cut from natural crystal. A slow deterioration of crystal grown from synthetic seeds requires that producers periodically start the process over with high-purity natural seed plates. High-purity silica sand represents the major potential competitor to lascas as the nutrient in growing cultured quartz crystals.

Whetstones, Hones, and Grindstones

Natural abrasives have been displaced by manufactured abrasive products made of materials such as fused aluminum oxide and silicon carbide. In most applications synthetic materials last longer,

making them more cost-effective, although whetstones, hones, and oilstones made from Arkansas novaculite continue to fill a niche in the abrasives markets. Some pulpstones still are fabricated from granite and other types of stone.

GOVERNMENTAL CONSIDERATIONS

Policies adopted by national governments can affect the availability, pricing, and consumption of some specialty silica materials. The Brazilian government, for example, established minimum prices for first-, second-, and third-quality Brazilian lascas in the export market, and in 1974 it embargoed shipments of lascas from Brazil. As a result, prices increased nearly sixfold that year and nearly tenfold subsequently. This action led to lascas production in the United States, Angola, and Namibia. Nationalization of lascas operations in Angola in 1979 and the civil war there have interrupted supplies of Angolan lascas since 1980.

In the past, the government of India followed policies that restricted exporting certain minerals. Then, in the early 1990s, India began to promote its minerals for export to generate foreign exchange earnings (Russell 1991).

Import Tariffs

Lascas for growing cultured quartz crystals and manufacturing fused quartzware products are imported into the United States free of tariffs for countries with normal trade relations. This applies to lascas designated as crude Brazilian pebble from Brazil and as quartzite from Namibia. No tariffs are levied on U.S. imports of other types of special silica stone such as flint or silex pebbles from Europe and metallurgical-grade quartzite from Canada. Although the United States is self-sufficient in industrial sand and gravel, Canada and Mexico are the largest U.S. trading partners in this regard, mainly because of their proximity to U.S. markets. No import tariffs are imposed on industrial sands of 95% or greater silica and not more than 0.6% iron oxide, or on industrial sand less than 95% silica. An ad valorem tax of 3% is levied on imports of piezoelectric quartz.

Depletion

For industrial sand or pebbles, the depletion allowance for federal income tax purposes in the United States is 14% for both foreign and domestic production. The rate allowed for natural electronic-grade (radio-grade) quartz crystal is 22% for domestic production and 14% for foreign production.

U.S. Stockpile

The United States designated natural electronic-grade quartz crystal as a strategic and critical material after World War II and purchased crystal from Brazil for the National Defense Stockpile (NDS). Since that time, the technology for growing synthetic quartz crystals has been developed and cultured quartz has now displaced natural crystals in essentially all applications. As a consequence, the NDS inventory has been reduced periodically by selling excess material on the open market, primarily for specimen and gemstone uses. The federal government reported that sales from the NDS during 2003 amounted to about 97,240 kg of natural quartz crystal valued at \$365,166. At the end of 2003, the NDS contained about 6,804 kg of natural quartz crystal (Dolley 2003).

Environmental Regulations

Most of the types of specialty silica materials discussed here are essentially entirely crystalline silica, which in its respirable form has been known to cause silicosis, a disabling pulmonary disorder. Ultrafine silica particles of about 0.5 μm are believed to constitute

the greatest health hazard because their surfaces exercise a strong oxidizing effect comparable to that of ozone. This effect is especially pronounced for quartz particles that have been recently ground, because freshly fractured and exposed surfaces are more chemically reactive than aged or weathered surfaces.

The silicosis risk associated with crystalline silica has caused consumers in some markets to abandon them in favor of alternative materials, in large part because of a monograph issued in 1987 by the International Agency for Research on Cancer (IARC). In that monograph, IARC classified crystalline silica as a Group 2A (i.e., probable) carcinogen in humans. The subsequent IARC data sheet listing suggested that all material safety data sheets for products containing 0.1% or more crystalline silica should contain a cancer warning. A number of federal and state agencies in the United States adopted that suggestion and require appropriate product labeling.

The facts and issues involved in the current crystalline silica debate are too many and too complex to be analyzed meaningfully here. They are addressed in more detail in other chapters of this volume, and they have had an adverse impact on demand for silica stone products. Because of the ongoing controversy, for example, one major U.S. manufacturer of abrasive media refused to introduce and market a new line of novaculite-based deburring media, despite the fact that more than 99% of all deburring operations are carried out in an aqueous environment where essentially no dust is generated.

PROBLEMS AND FUTURE TRENDS

The outlook for specialty silica materials, with the exception of ultrapure quartz grain and lascas, is not particularly attractive. Manufactured materials have already displaced natural silica in most abrasive and other industrial applications and can be expected to slowly penetrate the niches that remain, especially at the high end of the price range. This applies to novaculite for whetstones, hones, oilstones, and deburring media; sandstone as grinders and blocks for acid tank linings; quartz pebbles for acid tower linings and packing media and as the heat-transfer medium in air preheaters; quartzite and silex as blocks for grinding-mill linings and as pretumbled cubes for grinding and deburring; and pebbles of flint and silex as grinding-mill media.

At the low end of the price range, quartz gravel should continue to experience modest growth in demand for use in water filtration, partly because it faces little competition from cost-effective substitutes. There are likewise few substitutes for quartz gravel, quartzite, and perhaps high-quality novaculite for use as fluxes in ferrous and nonferrous metal smelting and as raw materials in the manufacture of silicon metal and various silicon alloys, although these end-use industries are typically highly cyclical.

Until means are devised for using high-purity silica sand instead, lascas should continue to be the untested feedstock in producing cultured quartz crystals for optics and electronics, particularly for products such as personal computers, electronic games, and cellular telephones. The markets for cultured quartz, and therefore lascas, are somewhat cyclical but should experience a higher rate of growth than most other markets for naturally occurring, specialty silica materials.

Overall annual growth in filtration markets is about 1% to 2%. Much of the growth is from demand in Eastern Europe, Asia, South America, and Central America. Mature markets in the United States and Western Europe also will continue to grow. Silica sand in rapid gravity filtration grew about 5% between 2001 and 2002. Pressure vessel and slow filter bed markets remained static (Taylor 2004).

The strongest rate of growth in demand should be experienced by ultrapure, fusing-grade quartz grain for specialty glass

and fiber-optic, precision optical, semiconductor, high-intensity lighting, electro-optical, and laboratory applications. Competition from synthetic silicas will intensify in these high-tech markets as the need for raw materials of higher and higher chemical purity intensifies. This need is driven largely by the trend to higher-capacity memory devices in the semiconductor industry, but also by developments in fiber-optic communications. Ultra-pure synthetic silica is produced by Sol-Gel technology, and commercial production of synthetic fused silica containing less than 2 ppm total impurities (including hydroxyl and chlorine ions) also is produced in the United States.

Although few commercial applications for specialty silica materials generate significant amounts of crystalline silica dust, silicosis and carcinogenicity issues will continue to adversely affect future market demand for these products. Producers willing to accept this situation should focus on developing resources of leucosil, ultrapure quartz grain, filtration-grade quartz gravel, and metallurgical-grade quartzite that are located close to geographic concentrations of major consumers.

Soda Ash

Ken Santini, Ted Fastert, and Ray Harris

INTRODUCTION

Soda ash is the common name for sodium carbonate (Na_2CO_3), an alkali compound that is one of the largest inorganic chemicals in terms of production of all domestic inorganic and organic chemicals, excluding petrochemical feedstock. Although most people have never heard of soda ash, it is an important industrial compound used to manufacture glass, chemicals, soaps and detergents, pulp and paper, and many other familiar consumer products. People have used natural alkalis for thousands of years; their industrial manufacture began in the last half of the 18th century.

Natural deposits of sodium carbonate were exploited as early as 3500 BC, when the ancient Egyptians used natural soda ash in making glass. They also mixed lime and soda ash to make sodium hydroxide (caustic soda), which was combined with silicate minerals from the Sinai Desert. This made soluble silica that, when added to a aluminum-rich silt from the Nile River, produced silica-aluminate cement mortar with excellent bonding properties for construction. Romans in the 1st century AD also used natural soda ash in glass manufacture but expanded its use to treat colic pains and skin eruptions and to make bread.

Elsewhere, people obtained alkali from wood ash. They learned over time that different types of wood yielded various ashes with different properties; therefore, various plants were burned specifically for their ashes. Ash from plants grown in salt-bearing soils (such as saltwort) and from kelp and other seaweeds, especially Spanish *barilla*, were so different from ashes obtained from other vegetation that it became known as soda ash (because of its sodium content) versus pot ash, a potassium-based alkali ash. About 13 t of *barilla* ashes produced 1 t of sodium carbonate and 14 kg of iodine as a by-product. The difference between the two ashes was relatively obscure until Duhamel Dumonceau made the distinction clear in 1736. The term *soda ash* developed from common usage and is perhaps better known today than its synonym, sodium carbonate. A primary source of soda ash is *trona*, a sodium-carbonate-bearing mineral whose name is traced back to Arabic origin. Trona also is known by other names such as *urao* (Venezuela), *kaum* (Nigeria), *natron* (from Greek *nitron* and Latin *natrium*), and *szeško* (Hungary).

The beginning of the Industrial Revolution in Western Europe in the mid-18th century soon put a strain on the availability of raw materials to meet consumer demands. One of these scarce materials was soda ash. Because of the Seven Years' War with England and the Napoleonic Wars with other parts of Europe, France could not obtain sufficient quantities of Spanish *barilla* or

other supplies of vegetable alkali to meet the growing demand. Efforts were needed to synthesize soda ash. In 1775, the French Academy of Sciences offered a large prize of 2,400 livres to anyone who could find an inexpensive method to make soda ash. In September 1791 at St. Denis, Nicolas Leblanc (1742–1806), a French chemist, developed such a technique using salt, sulfuric acid, coal, and limestone. The French Revolution interfered with its development and his patent and factory were confiscated, with Leblanc receiving only token compensation. Although Napoleon later returned the factory, Leblanc was not able to raise enough capital to reopen it, and he committed suicide in 1806. A small but not particularly successful Leblanc process plant was established in England in 1814. It was not until 1823 in Liverpool, England, that the process first became commercially successful. The process was introduced in Germany in 1843 and in Austria in 1851 (Harness and Coons 1942). Soda ash production by the Leblanc process reached its peak of about 599.5 kt in 1880, after which it began to decline as the Solvay process became more popular. The Leblanc process was used to a limited extent in Europe during World War I and had disappeared by World War II.

The Solvay process, also known as the ammonia-soda process, was developed by brothers Alfred and Ernest Solvay in 1861 based on a concept by Fresnel that had been known since 1811. For the next 50 years, implementing the concept evaded industrial chemists because no large-scale and economic means could be found to commercialize it. Although Ernest Solvay was unaware of the existence of an ammonia-soda concept, he solved the problem by using carbonating towers. The Solvay process produced soda ash from salt, limestone, and coke, with ammonia as a catalyst. With a capital investment of 136,000 francs, the Solvay brothers built the first plant at Couillet, Belgium, in 1863, and production began in 1865. Synthetic soda ash production was 1.5 tpd in 1866, and reached 10 tpd by 1872. Carbonating towers, patented in 1872, made ammonia-soda manufacturing a successful continuous process. Their second plant was built in 1872 at Dombasle, France. In 1874, the first Solvay plant in England was built at Northwich by Ludwig Mond, the namesake of Brunner Mond and Co. (formerly Imperial Chemical Industries), the company that currently operates the two English Solvay plants.

In the United States, William B. Cogswell in February 1879 heard a presentation on the Solvay process and sailed to Europe to meet with the Solvay brothers to seek their support for using their process in New York. At first, the brothers were not interested; Cogswell was as persistent, however, and ultimately gained their

support. The Solvay Process Co. was formed on September 21, 1881, and construction began immediately on the first Solvay plant at Geddes, near Syracuse, New York. The plant went onstream on January 10, 1884, and produced 11.18 kt in its first year of operation. In 1910, rotary calciners increased capacity to 1 ktpd. By 1930, plant capacity was up to 2.4 ktpd. The facility remained in continuous operation for more than 100 years. By 1939, 10 Solvay soda ash plants were in operation in 6 states. The Syracuse plant ceased production on January 6, 1986, and officially closed by February 1986. Ironically, this facility was the first Solvay plant as well as the last. Other than production from the first Solvay plant, most U.S. soda ash supplies during the 19th century came from imports. The remainder of the U.S. supply was obtained from small natural soda ash deposits in Nevada and California that served western consumers.

The first commercial natural soda ash operation in the United States began in Nevada in 1868 at the Ragtown Soda Lakes, better known as Big Soda Lake and Little Soda Lake, which are the remnants of extinct volcanoes about 7 km west of the present town of Fallon. Asa L. Kenyon, a pioneer who settled in the area in 1855 to sell provisions to settlers passing through, acquired the lake properties and in 1868 sold the smaller lake to Higgins and Duffy, who sold it to a San Francisco group known as Doe and Dowd. Little Soda Lake was primarily dry most of the year and reportedly had a mass of crystallized sodium carbonate on its surface that was more than 10 m thick, whereas Big Soda Lake was filled with water that was saturated with many salts, including sodium carbonate and borax.

Two types of solar processes produced the soda ash—a summer process in which trona precipitated in evaporation ponds on the perimeter of the lakes with soda ash being the final product, and a winter process in which natron precipitated with thermonatrite being the final product. Soda ash production from Little Soda Lake averaged about 300 tpy, whereas output from Big Soda Lake, which began operation in 1875, averaged about 450 tpy. Most of the soda ash was sold to miners in Virginia City, Nevada, to treat silver ore and to soap manufacturers in Reno, Nevada. Soda ash also was bagged and transported to Hazen, Nevada, where it was shipped by rail for \$19/st to San Francisco for further refining, after which it sold for between \$55 and \$65/st.

With the beginning of the Nevada Reclamation Project in 1902, the lake brines were increasingly diluted by infiltrating groundwaters from the Truckee–Carson irrigation project that conveyed water to California. By the end of 1907, the brines were so dilute that soda ash production became impractical and rising lake levels began covering the evaporation ponds and buildings. The soda ash producers brought claims against the U.S. government on June 17, 1917, citing that they believed there was a direct correlation between the flooding of their operations and the irrigation project, and that the government should be responsible for damages of \$205,000. On April 7, 1919, the U.S. Court of Claims decided in favor of the government. After years of appeals and investigations, which ultimately proved that the canals were responsible for the rising lake levels, the case was resolved on November 21, 1921, with the U.S. Supreme Court ruling in favor of the government. The case was a landmark decision because it set a new legal precedent that "... the government is not liable for all actual damages resulting from public improvements, but only for such damages as inevitable to result and which with due diligence and expert study could have been anticipated" (*San Francisco [CA] Bulletin* 1921). The fact that the soda ash producers gave a right-of-way to the government before 1907 was the main reason why they lost their case (Taylor 1987–1988). The right-of-way stated "that in consideration of the premises, the first party hereby releases the second party from all

claims and damages for entry, survey, or reconstruction of said works" (U.S. Supreme Court Case Nos. 26 and 32: *John Horstmann Co. v. U.S.* and *Natron Soda Co. v. U.S.*, October Term, 1921).

More than 85 years have passed since Big and Little Soda Lakes were flooded. Today, the two lakes lie quietly in the virtually barren landscape of western Nevada. No traces remain of the first natural soda ash operation in the United States except at the bottom of Big Soda Lake, which sometimes is explored by local divers to see the remains of the wooden buildings, rusting steam tractors, and beehive ovens that once produced soda ash. The site has been nominated for the National Register of Historic Places, a fitting tribute to this historic operation.

Natural sodium carbonate was also observed in other areas besides Nevada. In 1835, the Reverend Samuel Parker crossed the Rocky Mountains and noticed Epsom salts on the land surface near Independence Rock, Wyoming. As early as 1849, Mormon pioneers are believed to have used the natural sodium bicarbonate occurring along the Sweetwater River in Wyoming for laundry and medicinal purposes. The Western Alkali Corp. began commercial development of sodium carbonate brines there, producing *sal soda*, or washing soda, in solar evaporation ponds from 13 wells about 100 m deep. The operation ceased in 1920 because of high operating costs (Milani 1983).

The largest natural deposit of trona known in the world is at Green River, Wyoming. The deposit was discovered accidentally in January 1938 when the Mountain Fuel Supply Co. was drilling for oil and gas (Lindeman 1954). The company abandoned the well as a dry hole, but the company's geologist, William T. Nightingale, observed sodium carbonate in the drill cores at the well site. Core samples were sent to Roger C. Wells and Joseph J. Fahey of the U.S. Geological Survey (USGS), who verified the presence of trona. In 1940 Robert D. Pike, a consulting chemical engineer, recognized the economic potential of refining soda ash from the trona but not until he convinced the Westvaco Chemical Corp. (which merged with FMC Corp. in the fall of 1948) of this did commercial interest begin. In 1947, the first mine shaft was sunk about 460 m deep, and active mining began on a developmental basis later that year. Calcined trona was sold from 1950 (38,814 t mined and sold the first year) to 1953, when the first refined soda ash plant came onstream with an annual capacity of about 272 kt. Today there are four natural soda ash producers in Wyoming with a combined annual nameplate capacity of approximately 13.5 Mt (Kostick 2004).

Beginning with the first world energy crisis in 1973 and the growing international concern for the environment, worldwide synthetic soda ash output steadily decreased until 2001. During 2001, China added new Solvay process capacity and surpassed U.S. production of natural soda ash in 2003. Most of the world continues to use the Solvay process, which is energy, capital, and labor intensive and generates by-product calcium chloride and sodium chloride that cause environmental problems when discharged. In 2004, synthetic soda ash represented approximately 70% of total world production, with natural soda ash constituting the balance of about 30%. Of the estimated 40.3 Mt of total soda ash produced during 2004, 11 Mt of natural soda ash (approximately 27%) originated from the United States, with Botswana, Kenya, and China accounting for the remaining 3% (Kostick 2004, 2005).

GEOLOGY

Mineralogy and Physical and Chemical Properties

Several sodium-carbonate-bearing minerals are found in deposits throughout the world. The most important economic mineral is

trona (sodium sesquicarbonate), which has the following physical and chemical properties:

- Chemical formula: $\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2\text{H}_2\text{O}$
- Crystal system: monoclinic
- Cleavage: perfect on (100)
- Appearance: massive trona from Green River, Wyoming, deposits is clear to dark amber depending on impurities. Searles Lake, California, deposits are fine-grained masses to acicular and bladed crystals; clear to white to gray; and porous.
- Hardness: soft to semihard; 2.5 to 3.0 Mohs hardness
- Molecular weight: 226
- Specific gravity: 2.17 g/cm³
- Melting point: >70°C
- Solubility: 20 % maximum by weight in water; soluble in hydrochloric acid; when heated, loses water, the sodium carbonate dioxide.
- pH: 10.1 (1% solution)

The physical and chemical properties of soda ash (sodium carbonate–anhydrous) are as follows:

- Chemical formula: Na_2CO_3
- Appearance: white, granular solid
- Molecular weight: 105.99
- Specific gravity: 2.533 g/cm³
- Bulk density: 0.59 to 1.04 g/mL
- Melting point: 851°C
- Heat of formation (ΔH_f): 1,131 kJ/mol
- Solubility: 33% maximum by weight in water
- pH: 11.6 (1% solution)

Origin

Various theories have been proposed to explain the origin of sodium carbonate found in natural deposits. Different deposits may have been formed from a combination of one or more physical and chemical processes. These include (1) the evaporation of sodium carbonate–rich thermal spring water; (2) carbonation of sodium sulfide (from bacterial decomposition of sodium sulfate) to sodium carbonate; (3) ion exchange in sodium-bearing soils; (4) concentration–temperature–dependent equilibrium relationships among carbon dioxide, sodium bicarbonate, and carbonate that converts carbonate solutions to sodium bicarbonate, or carbon dioxide removed from sodium bicarbonate solutions to form carbonates; and (5) leaching of alkaline carbonates or basic–ultrabasic rocks. The sodium may have been derived from the leaching of sodic feldspars or volcanic ash deposits, and the carbon dioxide from the atmosphere and biogenic processes.

Most groundwaters in metamorphic or igneous terrains produce alkaline solutions on evaporation (Hardie and Eugster 1970). The relative absence of chloride and sulfate in these types of rocks permits solutions to become predominantly sodium- and carbon-dioxide-bearing. The chemical fractionation of inflowing waters and brines within closed depositional basins can produce different minerals accumulating in separate areas. The mechanisms can be mineral precipitation, selective dissolution of efflorescent crusts, degassing of brines, or redox reactions (Eugster and Jones 1979). Groundwater percolating through siliceous soils such as those developed on granite or windblown sands can become highly alkaline and enriched in sodium carbonate (Garrels and Mackenzie 1967). Very high carbon dioxide concentrations (up to 10% of soil gas) are known to occur in soils as a result of biological activity.

Table 1. Sodium-carbonate-bearing minerals

Mineral Name	Chemical Composition	Na_2CO_3 , %*
Thermonatrite (monohydrate)	$\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$	85.5
Wegscheiderite	$\text{Na}_2\text{CO}_3 \cdot 3\text{NaHCO}_3$	74.0
Trona (sesquicarbonate)	$\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2\text{H}_2\text{O}$	70.4
Nahcolite (sodium bicarbonate)	NaHCO_3	63.1
Bradleyite	$\text{Na}_2\text{PO}_4 \cdot \text{MgCO}_3$	47.1
Pirssonite	$\text{Na}_2\text{CO}_3 \cdot \text{CaCO}_3 \cdot 2\text{H}_2\text{O}$	43.8
Tychite	$2\text{MgCO}_3 \cdot 2\text{Na}_2\text{CO}_3 \cdot \text{Na}_2\text{SO}_4$	42.6
Northupite	$\text{Na}_2\text{CO}_3 \cdot \text{NaCl} \cdot \text{MgCO}_3$	40.6
Natron (sal soda or washing soda)	$\text{Na}_2\text{CO}_3 \cdot 10\text{H}_2\text{O}$	37.1
Dawsonite	$\text{NaAl}(\text{CO}_3)(\text{OH})_2$	35.8
Gaylussite	$\text{Na}_2\text{CO}_3 \cdot \text{CaCO}_3 \cdot 5\text{H}_2\text{O}$	35.8
Shortite	$\text{Na}_2\text{CO}_3 \cdot 2\text{CaCO}_3$	34.6
Burkeite	$\text{Na}_2\text{CO}_3 \cdot 2\text{Na}_2\text{SO}_4$	27.2
Hanksite	$2\text{Na}_2\text{CO}_3 \cdot 9\text{Na}_2\text{SO}_4 \cdot \text{KCl}$	13.6

* Includes bicarbonate converted to carbonate.

This can produce more than 200 mg/L of carbon dioxide in the soil water (Jakucs 1977). The Pretoria Plain in the Republic of South Africa, the sandhill regions of Nebraska, and the Sind of Pakistan are examples of sodium carbonate in soil waters (Barbour 1916; Cotter 1923; Dutoit 1948). In lakes, the continual generation of CO_2 by algae and bacteria can aid deposition of monomineralic beds of trona (Eugster 1971). Semiarid rather than arid climates are most favorable for producing alkaline waters because the evaporation rate is too rapid to stabilize the soda solutions in very arid regions (Perelman 1967).

In sedimentary rock terrains, the drainage usually contains too much chloride, sulfate, and calcium to produce either brine or solid sodium carbonate salts. Although sodium carbonate solutions originate from the weathering of igneous rocks, these same waters can interact with other waters or with other rock and soil types in the area of accumulation so that mixed chloride and sulfate salts are the final products (Risacher, Echeñique, and Ballivian, unpublished data).

Mode of Occurrence

Sodium carbonate resources commonly occur as precipitates in shallow, nonmarine alkaline lakes and marshes and usually coexist with various chloride and sulfate salts. For this reason, it is not uncommon to find different sodium-carbonate-bearing minerals within the same deposit. Table 1 lists some minerals that contain sodium carbonate in varying concentrations.

Because sodium carbonate generally was deposited in shallow bodies of water, many of the deposits were subjected to vast seasonal changes in area and mineral concentration, and were susceptible to destruction by mechanical and chemical erosion caused by the relative softness and solubility of the minerals. Therefore large economic sodium carbonate deposits are relatively rare and are considered geologically young, ranging from the Eocene to Pleistocene epochs. Pre-Tertiary deposits are virtually absent from the geologic record.

Mannion (1975, 1983) presented a list of the more common forms of sodium carbonate occurrences:

1. Natron crystals in cool, wet environments on the bottoms of ponds or at shallow depths in salt marshes, as at Lake

- Goodenough, British Columbia (Cummings 1940), and Owens Lake, California (Smith and Friedman 1975)
2. Powdery surface efflorescences of the monohydrate around alkaline lakes or marshes, as in the alkaline soils of the lower Danube River Valley, Hungary, and at Lake Nyasa, Tanzania (Orr and Grantham 1931)
 3. Relatively hard but porous deposits of trona, either around the shores or at the bottoms of shallow alkaline lakes or playas, as at Lake Magadi, Kenya (Baker 1958; Eugster 1970), Owens Lake, California (Dub 1947), and Lake Chad Basin, Africa (Eugster and Maglione 1979)
 4. Older beds of buried trona, nahcolite, or other sodium-carbonate-bearing minerals, as the Green River Formation in Wyoming (Bradley and Eugster 1969; Culbertson 1971; Deardorff and Mannion 1971; Wiig, Grundy, and Dyni 1995; Leigh 1998), in Colorado (Smith and Milton 1966; USBM 1972), and at Railroad Valley, Nevada (Free 1913)
 5. In solution as a constituent of brine, either surface or subsurface, as at Searles Lake, California (Smith 1979), and Makgadikgadi, Botswana (Massey 1973; Lefond 1981)

Although certain deposits are made up of combinations of the five forms of occurrences, sodium carbonate deposits can be classified by their economic importance (Kostick 1983). The five forms, ranked by decreasing potential economic significance, are buried, surface or subsurface brines, crystalline shoreline or bottom crusts, shallow lake bottom crusts, and surface efflorescences.

Occurrences of Sodium Carbonate

Large and small natural deposits containing sodium-carbonate-bearing minerals exist in several countries throughout the world. Most of the deposits contain solid salts, solutions, or both.

Most of the deposits listed are geologic occurrences and are neither large enough nor of sufficient sodium carbonate content to be of economic potential. Many small-scale deposits such as those in Chad and the Sudan have been mined strictly for local consumption.

Africa

Africa has numerous sodium carbonate occurrences scattered throughout the continent. The arid to semiarid climates in parts of Africa prevent the dissolution and transport of the soluble carbonate minerals. Some of the occurrences are small, isolated lake deposits whereas others are major deposits found in a chain in the East African Rift Valley. Garrett (1992) contains an excellent description of all the major and minor soda occurrences in the Rift Valley.

A \$504 million natural soda ash facility commenced production in April 1991 on the Sua Pan in the Makgadikgadi Basin in northeastern Botswana. The project is operated by Soda Ash Botswana (SAB), a joint venture between the government (48%) and the African Explosives and Chemical Industries (AECI) consortium (52%) with its partners AECI (25.5%); the Anglo American Corp. (12.75%); and De Beers Holdings (12.75%). The facility produces about 300 ktpy of refined soda ash from underground brines and 600 ktpy of sodium chloride. Most of the soda ash is marketed in South Africa, which had relied heavily on soda ash imports from the United States. SAB also exports soda ash to Zambia and Zimbabwe, both using about 15 kt annually. The sodium carbonate reserves at Sua Pan exceed 360 Mt.

Impure sodium carbonate in the form of natron mixed with halite has been obtained from crystallizing pans among sand dunes in the northeastern section of Lake Chad (Eugster and Maglione 1979). Most of the crude material has been for local consumption;

it had been reported, however, that a few thousand tons of crude trona had been previously exported to Nigeria. Some of the reported uses are as follows:

- People use it as a remedy for stomach aches and constipation.
- People mix the natron with ashes of burned wheat stalks to make a crude soap.
- Chadian herders give it to cattle as a salt lick.
- People mix it with raw tobacco to flavor it for chewing.
- Tanners use it as an additive with certain tree gums to tan hides and skins.

Wadi Natron in Egypt, about 80 km northwest of Cairo and 35 km west of the Nile River, consists of up to 20 individual lakes, some of which dry completely during the summer (Lucas 1912; Atia, Hilmy, and Bolous 1970). Trona obtained from these lakes has been used for more than 5,500 years. Soda ash was used to make ornamental glassware and in the mummification process. Samples of trona have been found in one of the pharaohs' tombs at Thebes, suggesting the importance of its unique value. Other occurrences have been reported at El Barnugi in Lower Egypt, at Mahamid, and at Wadi Tumilat in Upper Egypt. Trona has been identified in cores taken from the outer Egyptian shelf of the Nile Cone in the Mediterranean Sea. The trona probably was eroded from the continental margin 18,000 to 23,000 years ago and buried very quickly in the deep marine environment (Stanley and Sheng 1979). Ethiopia has several sodium-carbonate-bearing lakes. The lakes in the southern part of the Rift Valley are richer in sodium carbonate than those in the north.

The second major natural soda ash facility in Africa operates at Lake Magadi in Kenya. The 65-km² deposit is probably the largest of all those in the Rift Valley. Trona has been mined since 1914 by the Magadi Soda Co., Ltd., owned by Brunner Mond Holdings, Ltd. (formerly Imperial Chemical Industries; the parent company of Brunner Mond and Co.). The trona is excavated by bucket dredgers mounted on a floating pontoon. The ore is crushed and made into slurry so that it can be pumped through a floating pipeline to a refinery on the shore. The slurry is screened, washed, rescreened, and dewatered to remove salt and mud. The trona is calcined to remove the CO₂ and converted into soda ash. The operation has an annual production capacity of about 350 kt.

The lake bed is underlain by about 45 m of relatively pure trona with some interbedded trona and trona-bearing muds. The sodium carbonate content of the trona is approximately 45.2% and the sodium bicarbonate content is about 35.7%; this equates to ~68% sodium carbonate equivalent. Brine is found within 1 m of the surface. The alkaline spring water that delivers the sodium carbonate to Lake Magadi is considered to be the result of weathering and leaching of igneous silicate minerals (Baker 1958). Dilute groundwater from the igneous highland regions recharges a deep reservoir, which in turn supplies the warm springs with concentrated carbonate waters (Eugster 1970). The same process appears to be responsible for the alkaline waters at Lake Natron, Lake Nakaru, Lake Elmenteita, and Lake Bogoria (Orr and Grantham 1931). Based on the flow rates of the rivers and springs and the rate of evaporation, it is estimated that about 200 kt of new trona crystallizes annually in Lake Magadi (Garrett 1992).

An alkali lake is located in Malawi in a downfaulted rift basin. Alkaline hot springs and alkaline igneous intrusives in the area were the presumed source of the sodium carbonate in Lake Chilwa. Trona, or *kaum*, is found in many small lakes and in alkaline soil in Nigeria. It also accumulates as effervescent crusts on the surface of a sandy area in Dallol Bosso in western Nigeria (Garrett 1992).

Several pans in Namibia contain sodium carbonate that the local population has used for centuries. In the Owambo Basin, the two Otjiwalunda pans (No. 1 and No. 2) have been known since 1915 and contain trona (78.65%); salt (0.31%); thenardite (0.94%); and burkeite on the surface (Dutoit 1948; Schneider and Genis 1991). The deposit grades from almost pure trona to trona mixed with other salts. A rare sodium carbonate mineral, pirssonite, was reported to occur with the thenardite from the No. 2 Otjiwalunda Pan. Also in the Owambo Basin are the Ngandjela Pan and the Ngandjela East Pan, which also contain halite and trona intermixed with thenardite. The Naruunda and Onanzi pans that are also located within the region contain brines enriched with various sodium-bearing minerals. Production has ranged from 70 to 4,189 t.

The Pretoria Salt Pan in the Republic of South Africa is an extinct volcanic crater containing sodium carbonate. The first commercial development began in 1912 when the government leased to P.A. Ogilvie the rights to mine crude trona from the deposit. The lease was ceded later to South African Alkali Ltd., which mined about 400 t in 1914. Calcined trona was produced from 1915 to 1918 and refined soda ash from 1919 to 1922. Most of the calcined trona was used to neutralize the acidity of the mine water at the Witwatersrand mines (Wagner 1922). About 19 kt of trona were produced from the Pretoria Salt Pan during its brief operation.

At Bir El Natron in Sudan, a large deposit of trona is found mixed with halite and burkeite. Trona comprises about 35% of the ore body. Some production has been reported, but quantitative information is not available. Chataud (1890) reported the occurrence of trona near Fezzan in the Sahara. In Tanzania, Lake Natron is a large sodium carbonate deposit containing an estimated 150 Mt of soda ash resource covering 1,039 km². It is about 30 km south of Lake Magadi in Kenya. Total resources may be about 1 Gt when including the additional sodium carbonate brines and crystals intermixed with mud layers. Lake Natron lies in the eastern Rift Valley, which contains additional sodium carbonate deposits in other countries. The brine concentration and composition of Lake Natron is nearly identical to that of Lake Magadi in Kenya. The source of the sodium carbonate in Lake Natron originates from three carbonatite volcanoes, including the active Oldoinyo Lengai volcano, which erupts with sodium carbonate lava and ash. Several studies have been made to develop the deposit, the most recent in 1990. Lake Eyasi in Tanzania is also an alkaline lake that has produced some crude soda ash on a limited scale.

Lake Katwe in Uganda contains trona, burkeite, and hanksite that formed when about 50 small springs reacted with carbonatite and other volcanic rocks in the area. Approximately 5 kt of crude trona are recovered from the lake annually.

Antarctica

Although there are no reported deposits of trona on this continent, occurrences of efflorescences of various sodium salts have been documented in the Vestfold Hills, Bunger's Oasis, and McMurdo Sound regions (Dort and Dort 1970). Some evaporite minerals found are halite, mirabilite, thenardite, and bloedite, which are commonly associated with sodium carbonate deposits elsewhere in the world.

Asia

China, Mongolia, India, Pakistan, Tibet, and the former U.S.S.R. are known to have several sodium carbonate occurrences. Some of the geologic and mining information regarding sodium carbonate deposits in Asia is old, nonexistent, or unavailable for many of the occurrences. Some new information was published within the past decade and is included here.

More than 50 sodium carbonate deposits have been reported in China. China has several alkali lakes and at least two major buried trona deposits, in the 265-km² Wucheng Basin and at Anpeng in the 13-km² Biyang Basin, both in Henan Province.

The Eocene Wucheng deposit was discovered in 1971 during petroleum exploration. The deposit contains 36 trona horizons that are interbedded with oil shale and argillaceous dolomite (Lu 1998; Zhang 1998). They cover 4.66 km² and are buried 643–974 m below the surface. The lower 15 trona beds typically are 0.5–1.5 m thick, with a maximum of 2.38 m. These beds contain 40%–60% sodium carbonate and 0.3% sodium chloride. The upper 21 beds contain halite and are generally 1–3 m thick, with a maximum of 4.56 m. These beds contain 20%–40% sodium carbonate and 20%–60% sodium chloride. Resources are reported to be 37 Mt of sodium carbonate equivalent. The deposit is solution-mined and feeds a soda ash plant.

The Eocene Anpeng nahcolite deposit was discovered in 1976 during petroleum exploration. It is 60 km southwest of the Wucheng trona deposit. The nahcolite beds occupy 8 km² at depths of 1.3–2,520 m (Lu 1998; Zhang 1998). Seventeen nahcolite beds ranging from 0.6 to 3.6 m in thickness have been identified. They are associated with oil shale, dolomite, and sandstone. This deposit is also solution-mined to produce soda ash. Northwest of the area of the nahcolite beds, sodium bicarbonate and sodium carbonate brines occur in porous dolomite in beds 1–5 m thick. The nahcolite beds range from 48% to 95% sodium bicarbonate and up to 40% sodium carbonate.

Several soda lakes or *nor*s are found in Inner Mongolia, such as in the Ju League and Xilin Gol League, and in other areas of China, such as in Hami in Xinjiang Province. The Quaternary Qagan Nur deposit, also known as the Chaganor deposit in Inner Mongolia, contains 11 Mt of sodium carbonate and is the largest. It occurs in a basin with an area of 21 km². Nine trona beds ranging in thickness from 0.6 to 3.47 m are present. Sodium carbonate content ranges from 26% to about 29%. The main minerals are trona and natron associated with mirabilite and halite. This deposit also supplies feedstock to a soda ash plant. Zhang (1998) describes other small deposits—the Ordos alkali lakes in Inner Mongolia.

Sodium carbonate is found with mixed salts in India in alkaline soils, lakes, and brines. Sambhar Lake and Lonar Lake, which is the world's only known basalt impact crater, contain about 22 Mt of soda ash reserves (Fredriksson et al. 1973). Lonar Lake contained about 85 m³ of brine in 1910 and produced about 600 t of soda ash in 1903. Up to 20 kt of crude trona was mined annually from various sources at different times in the 20th century.

In Pakistan, several hundred small shallow lakes contain sodium carbonate, chloride, and sulfate. Some of the lakes have trona crusts and natron, which crystallizes during the winter.

Several sodium-carbonate-bearing lakes such as Zabuye Caka, Bangkog Cuo, and Guogaling Cuo are reported in the Qinghai-Xizang Plateau of Tibet. Trona, natron, the monohydrate, halite, northupite, mirabilite, and hydromagnesite are commonly associated with the brine. Potassium, lithium, rubidium, and cesium alkali metals are associated with sodium chloride, sulfate, and carbonate ions—similar to the chemical composition of Searles Lake, California, and certain lakes in South America.

The Kazakhstan and the Kulundinsk depression of Altay near Slovgorod and Barnaul in Siberia have produced some natural soda ash from alkali lakes containing natron and brine. Alkali lakes have also been reported near Chita in eastern Siberia; in the Araxes Plain of Armenia; in Kazakhstan; in Krasnaya Polyana, the Kazakh-Tauz region of Azerbaijan; and in the Carpathians. Most of these lakes are too small and remote for large-scale commercial development.

Plants to produce soda ash from natural soda sources have been built at Lake Tanatar and the Petukhov Lakes, both near Mikhaylovskiy (Batalin, Stankevich, and Kasimov 1974). Natural soda ash production in the former U.S.S.R. reached its peak in the 1950s with only about 60 kt of output (Shabad and Sagers 1987). Soda ash has also been produced as a by-product of alumina refining from nepheline syenite (a sodium–potassium–aluminum silicate) at several locations, including the Pikalevo plant in Leninograd Oblast. The Kola Peninsula is the primary location where the nepheline syenite is a coproduct with apatite. The nepheline is sintered with limestone in rotary kilns to produce alumina, soda ash, potash, and cement. The alumina content in the nephelinite was only about half that of bauxite; the process was considered to be economical because it produced coproducts.

Australia

Although salt pans containing sodium chloride and sodium sulfate are common in Australia, there are no significant surface occurrences of sodium carbonate. Alkaline springs occur near Herbertson, Queensland. In the Bowen and Sydney basins of Queensland, dawsonite has been found, some of which reportedly occurs as alterations of other minerals from sodium carbonate mineralization formed by the leaching of alkaline or ultrabasic rocks.

A sodium bicarbonate bearing brine (1.6%–2.5% NaHCO_3) was discovered at a depth of 600–1,100 m while exploring for petroleum. Resources have been estimated to be between 500 Mt and 1 Gt of sodium carbonate equivalent. Additional exploration and drilling may locate a trona or nahcolite source of the brine.

Europe

Saline and alkaline lakes are not common in Europe because the present climate is not conducive for development. Sodium carbonate efflorescences have been reported near Szeged in the Danube Valley in Hungary. Chatard (1890) reported processing of the crude soda (known as *szekso*) into refined soda ash. Alkaline brines have been found in Fulophasa, Hungary, at depths of 30 m. Trona and searlesite have been reported in Miocene lacustrine marls and clays in northern Bosnia.

Turkey is the third country in the world that has known buried trona deposits. The Beypazari deposit is approximately 100 km northwest of Ankara. The deposit was discovered in 1982 during drilling for lignite. Based on drilling, the deposit covers about 8 km² in the Beypazari Basin. The trona is associated with shale in the lower part of the Miocene Hirka Formation. Trona beds were deposited as two lens-shaped bodies within a zone 70–100 m thick in the lower part of the shale unit. A total of 33 trona beds have been identified: 16 in the lower trona lens and 17 in the upper lens. The total thickness of the lower trona sequence is from 40 to 60 m, and the total thickness of the upper trona sequence is about 40 m. The interval between the lower and upper lenses ranges from 30 to 35 m. The total thickness of trona beds in both lenses varies between 21 and 34 m in the central part of the deposit and between 2.5 and 12 m along the margins. The thickness of individual trona beds in both horizons ranges from 0.4 to 2 m. The principal sodium carbonate minerals are trona and nahcolite. Sodium oxide content of the trona ranges from 37% to about 42%, and the nahcolite content ranges from 30% to approximately 36%. Proven reserves are estimated at 210 Mt (Helvacı 1998). Feasibility studies and joint venture proposals to develop the Beypazari resource have been conducted since the mid-1980s. In 1983 the state-owned mining group Etibank (later named Eti Holding) held the trona deposit. Eti Holding sought a private-sector partner in 1998. The Park Group was awarded 76% interest, with Eti Holding a 22% share, and the state-

owned Vakıfbank was awarded a 2% share in Eti Soda. In 2004, the Export–Import Bank of the United States received an application to finance \$50 million in U.S. equipment and services to construct an operation that would have an annual production capacity of 1 Mt of soda ash. There was no decision regarding the status of the project by the end of 2004 (*Industrial Minerals* 1999, 2002; Kostick 1999, 2002, 2004).

Rio Tinto Madencilik (a subsidiary of Rio Tinto Minerals Development Company) discovered a second deposit in 1998 at Kazan, about 35 km northwest of Ankara. The deposit contains 12 trona beds that range in depth from 420 to 850 m, with estimated resources of 607 Mt at an average grade of 31% trona. The deposit is low grade in comparison to the Green River, Wyoming, trona deposit. The trona will be solution-mined using directional horizontal drilling technology. This technology is currently being used in the Piceance Creek Basin, Colorado, to mine nahcolite. Beginning in 2004, Rio Tinto initiated a 3-year pilot project to determine the viability of solution mining. Small-scale production is planned to begin in 2007, with projected startup of a 900-kt py soda ash plant scheduled for 2011 (*Industrial Minerals* 2002, 2003a; Kostick 2002, 2003).

North America

Soda ash occurs in natural deposits found in Canada, Mexico, and the United States. The largest trona resource discovered to date is near Green River, Wyoming.

Canada. There are several small soda ash deposits in British Columbia, in western Canada. They tend to be located in the same zone that extends into the saline lakes of Washington. Commercial production of soda ash was reported from some of the deposits between 1928 and 1945. Most of deposits are located in shallow basins in glacial drifts overlying basaltic lava flows. The sodium carbonate is primarily found in brines with some surface crystal layers and crusts. Cummings (1940) estimated that the soda lakes in British Columbia contained about 103 kt of sodium carbonate reserves.

Mexico. Several alkaline thermal springs, subsurface brines, thin crusts, and surface efflorescences contain sodium carbonate in various locations in Mexico. Until it was closed in 1994, the only other natural soda ash operation in the Western Hemisphere outside the United States was at Lake Texcoco, 20 km northeast of Mexico City at San Cristóbal Ecatepec. In about 1900, three lakes comprised a large part of the region: Texcoco, Xochimilco, and Chalco. The last two contained potable water, whereas Texcoco consisted of brackish water. Fearing that Mexico City might be flooded, Texcoco was allowed to dry by diverting feeder streams to canals. The hot climate accelerated the evaporation rate and concentrated the brines that percolated down through the lake-floor clay sediments. The brine tends to concentrate on top of two impermeable zones about 53 m deep. The upper zone is richer in sodium carbonate and contains about 120 Mt of sodium carbonate resource, whereas the lower zone contains about 40 Mt. Additional sodium carbonate probably was introduced by local volcanic activity from two volcanoes—Popocatepetl and Ixtaccihuatl—120 km to the south of the deposit. Andesitic volcanics also occur east and west of Mexico City. The resource covers about 52 km².

A small pilot plant was constructed in 1940, and production of soda ash began in 1948 with a capacity of about 100 tpd. More than 512 wells in the deposit collect the subsurface brines, which are sent to a spiral solar evaporator that is 841 ha in area and 50–60 cm deep. The incoming brine was concentrated from 4% (sodium carbonate content) to 6%–7% in the rainy season and 9%–10% in the dry season. Weaker brine would stay in the outside perimeter of the

concentrator for about 1 year and in the inside perimeter, where the maximum concentration occurred, for about 6 months. The concentrated brine was pumped from the center of the spiral concentrator to the nearby soda ash refinery where it was carbonated into sodium bicarbonate and then calcined into soda ash. Until September 1988, a subsidiary of a government-controlled holding company operated the facility. In 1994, a private group owned the 200-ktpy operation.

Another sodium carbonate resource in Mexico is located at Bahia de Adair on the northern coast of the Gulf of California; it was first described in 1898. The area consists of four small playa lakes. The highest concentration of sodium carbonate occurs at depths from 6 to 19 m. Crusts on the surface average about 31% sodium carbonate. Exploration of the area did not detect any significant buried trona deposit. In 2002, Minera MGM de CV (a wholly owned subsidiary of Morgan Minerals, Inc., of Toronto, Canada, and Productos Químicos Roda SA de CV of Torreón, Coahuila, Mexico) formed the joint venture company, Tronamex SA de CV. The company planned to develop the Adair trona deposit in Sonora, approximately 20 km north of Puerto Penasco on the east coast of the Sea of Cortez. Resources are estimated at 100 Mt, of which about 80% is in subsurface brines. The initial plan is to mine a shallow trona bed (0.3–2 m thick) and to solar-evaporate brines to produce an animal-feed additive. The company produced a small amount of product in 2003 and 2004 (*Industrial Minerals* 2001, 2003b; Kostick 2001, 2003).

Other occurrences in Mexico are deposits in Chihuahua; the Durango, Sayula, and Zatecas basins; Lake Cuitzeo; Valle de Santiago; and Laguna de Xaltocan and Laguna de Zumpango, both in the Valley of Mexico (Garrett 1992).

United States. Sodium carbonate occurrences are found in Alaska, California, Colorado, Nebraska, Nevada, Oregon, Utah, Washington, and Wyoming.

Near Owens Lake, California, human activities since the early 1860s have resulted in several episodes of high evaporation. In conjunction with the lack of outflow from Owens Lake, these episodes caused the deposition of saline minerals such as trona and associated sediments. Between 1861 and 1917, increased withdrawals from the Owens River for agricultural purposes greatly reduced water inflow to the lake. In 1913, the Los Angeles Aqueduct was completed, which diverted virtually all the remaining Owens River flow from Owens Lake. By 1926, Owens Lake had reached its current condition, which is essentially dry with small areas of highly concentrated brine occurring at certain times on the surface of the lakebed. Owens Lake is 4.9 km long by 3 km wide with an area of 87 km².

From 1960 to 1993 various companies drilled more than 1,000 auger, drive-pipe, and core holes. Based on the drilling data, the evaporite deposit has a maximum thickness of 3 m. The evaporite deposit is exposed at the surface and consists of various horizons of crystalline material overlying lake-bed sediments. In cross section, the deposit is lenticular, with the thickest section near the western side of Owens Lake (Santini and McCormick, unpublished data; Brown, Lamos, and Scarr 2004).

Approximately 70% by weight (or 65% by volume) of the porous evaporite deposit comprises various minerals, and about 30% by weight (or 35% by volume) is interstitial brine. Trona is the predominant mineral present in the evaporite section. Other minerals are burkeite, thermonatrite, and halite. The chemical composition of the evaporite deposit is 41.5% sodium carbonate and 25.0% sodium bicarbonate; this equates to ~57% sodium carbonate equivalent. In addition, various amounts of sodium chloride and sodium sulfate are present. The most recent reserve estimate

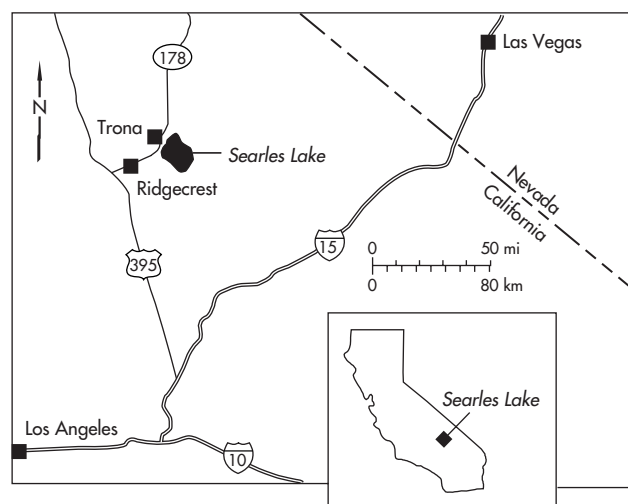

Figure 1. Location of Searles Lake, California

(1996) is 100 Mt of evaporite minerals in situ, of which approximately 52 Mt of sodium carbonate equivalent is present.

The first natural soda ash operation in California began in 1887 at Keeler, on the northeast shore of Owens Lake (Ver Planck 1959). The Inyo Development Co. constructed solar evaporation ponds that were filled with lake water at the beginning of warm weather. The brine was allowed to evaporate until it reached a density of 30°Be, after which trona began to crystallize. If unwanted salts began to form, the operator drew off some of the mother liquor and replaced it with fresh lake water. At the beginning of October, the ponds were drained and the harvesting of trona, which was about 1.9 cm thick, began. The trona was converted to a 95% pure soda ash product by heating it in beehive furnaces to remove the water of crystallization and excess carbon dioxide contained in the sodium bicarbonate. By 1900, Inyo had an annual capacity of 10 kt. Other natural soda ash companies set up operations on the perimeter of Owens Lake in the early 20th century and prospered for several decades until the late 1960s, when competition from Wyoming natural soda ash increased. Lake Minerals Corp. controlled the deposit in 1981, when Cominco American, Inc., acquired the company. In 1989, Cominco and Vulcan Chemicals formed the joint venture company, Owens Lake Soda Ash Co. The objective was to begin soda ash production by 1997, but, eventually, the decision was made not to proceed, and subsequently Lake Minerals was acquired by U.S. Borax Inc. In 2005, Lake Minerals Corp. mined crude trona from the surface for use at its Boron, California, operation as a reagent in the production of borate products.

Searles Lake, California, is a large playa lake deposit occupying the lowest part of Searles Valley, a closed structural basin filled with alluvium and nonmarine evaporates (Moulton and Santini 1995). The playa lake deposit is 16 km long by 10 km wide with an area of about 104 km² (Figure 1).

In Searles Lake, brine-bearing evaporite horizons alternate with mud beds. Three major subsurface evaporite horizons have been identified and are termed, from bottom to top, the Mixed Layer, Lower Salt, and Upper Salt. The evaporite beds were formed by desiccation of runoff from the eastern Sierra Nevada during Quaternary time. The resulting beds are generally thicker in the lake center, then thin and pinch out at the edges of the lake.

The saline beds are generally brine saturated, white to pink, hard, and very porous. The important ions are sodium, potassium,

carbonate, bicarbonate, sulfate, chloride, and borate. These ions are present in the brines in various concentrations, and combine to form the major evaporite minerals trona, nahcolite, halite, hanksite, burkeite, borax, theardite, sulfahalite, and glaserite. The mud beds, in general, are dark green to brown, soft, porous, and may have a distinct mercaptan (rotten egg) odor. The stratigraphic section from bottom to top is as follows:

1. The Mixed Layer is a sequence of mud and evaporite beds about 67–95 m below the surface. The lower Mixed Layer is divided into several units based on mineral composition. These deeper beds contain trona, but also halite and theardite. The upper Mixed Layer is divided into several units based on differences in electrical conductivity and mineral composition. These horizons are predominantly trona, which are solution-mined for soda ash production.
2. The Bottom Mud is 30 m or greater in thickness and forms a bowl-shaped body composed of mud beds containing saline minerals.
3. The Lower Salt ranges in thickness from approximately 12 m in the playa lake center to zero at the edges. The unit is composed of seven evaporite beds separated by six mud beds. These evaporite horizons are predominantly trona and halite, although borax, burkeite, nahcolite, and northupite are also found.
4. The Parting Mud is 3 m thick in the playa lake center and thickens to 8 m or more toward the edges, and contains some saline minerals.
5. The Upper Salt ranges from 23 m at the playa center to zero along the edges. The horizon can be divided into two units. The lower unit is generally thinner in the playa center and thickens toward the edges, before it pinches out. It is composed mostly of trona and halite, with minor amounts of burkeite and theardite. The upper unit is thickest at the playa center and thins toward the edges. It is composed of halite and hanksite, with some trona beds, and minor amounts of borax and sulfahalite.
6. The Overburden Mud consists of a central halite facies, approximately 7 m thick, which grades toward the edges to a mud facies that is up to 10 m thick.

The Searles Lake sodium carbonate resources have been reported to be 1.06 Gt. In addition, there are substantial resources of sodium borate, sodium sulfate, potash, and sodium chloride (Fairchild, Lovejoy, and Moulton 1998). The sodium carbonate content of the brines are Mixed Layer, ~6.5%; Lower Salt, ~5.5%; and Upper Salt, ~4.4%.

John Wemple Searles, who discovered borax crystals on the surface in 1862, first recognized the economic potential of Searles Lake. Although he and his brother Dennis formed the San Bernardino Borax Mining Co. in 1873, it was not until 1908 that the California Trona Co. was formed to produce soda ash using the equipment from the Searles' old borax plant. The operation never succeeded, and the plant went into receivership in 1909. The American Trona Corp. was organized on June 12, 1913, and acquired the properties of the California Trona Co. An embargo on German potash because of World War I prompted the company to produce potash rather than soda ash. On June 4, 1926, the American Potash and Chemical Co. (which acquired American Trona Corp.) was formed, but it was not until 1931 that the first soda ash was produced at the Trona plant. The company merged with Kerr-McGee Chemical Corp. on December 29, 1967. Soda ash production at the Trona plant ended in July 1979 because of equipment obsolescence and rising operating costs, and because the company brought onstream

its Argus soda ash facility, adjacent to the Trona plant, which continued to produce boric acid, potash, and sodium sulfate coproducts.

The Argus plant was designed to produce only natural soda ash. It was commissioned in July 1978 and currently has a nameplate capacity of 1.45 Mt.

Kerr-McGee also operated a second soda ash plant known as the Westend plant that it acquired from Stauffer Chemical Co. in October 1974. The plant originally was built in 1918 to produce borax but experienced operating problems. Borax was successfully produced in 1926 and soda ash in 1927 by the Westend Chemical Co., which ultimately merged with the Stauffer Chemical Co. in 1956. The operation continued to produce soda ash until January 1988. Kerr-McGee sold all the Searles Lake facilities to North American Chemical Co. on December 1, 1990. IMC Global acquired the chemicals and salts businesses in 1998 and in 2004 sold these interests to Searles Valley Minerals.

The Piceance Creek Basin is located in northwestern Colorado. It has an areal extent of approximately 18,700 km². The basin contains the second-largest known sodium carbonate resource in the world. Potential sources of sodium carbonate are nahcolite and dawsonite (sodium–aluminum carbonate). The Parachute Creek Member of the Eocene Green River Formation contains nahcolite, dawsonite, and halite (saline minerals) associated with oil shale. These saline minerals are found primarily in the north-central area of the Piceance Creek Basin. The saline minerals are generally limited to the lower part of the Parachute Creek Member. The main concentration of nahcolite occurs in the Saline Zone that has a maximum thickness of about 335 m. This zone contains oil shale, oil shale with disseminated nahcolite (crystals and crystal aggregates), bedded nahcolite, and bedded halite. There are 26 nahcolite horizons present in the Saline Zone. Only the Boies, Love, Greeno, and TI beds, however, are greater than 60% nahcolite and greater than 2 m in thickness. The Boies bed is the highest quality and has the greatest thickness of all the nahcolite horizons. It contains about 80%–85% nahcolite and is up to 9 m thick. It is currently solution-mined for sodium bicarbonate. Past solution mining for sodium carbonate production targeted the Saline Zone with 23% nahcolite and less than 1% halite. The nahcolite-rich Boies bed is not present in this area. As a result, the minable horizons are oil shale with disseminated nahcolite and the thinner nahcolite beds (i.e., the Love bed, etc.) previously mentioned (Santini, unpublished data; Day and Santini 1997; Day 1998; Hardy et al. 2003).

Resources of 29 Gt of nahcolite and 17 Gt of dawsonite, equivalent to 18 and 6 Gt, respectively, of soda ash resources, are available as single-mineral extraction or as a by-product of oil shale processing (Dyner 1980). Commercial development to mine nahcolite in conjunction with oil shale was proposed in the early 1980s; leasing obstacles and economic problems, however, prevented successful commercialization. Single-mineral extraction using solution mining on sodium leases began as a pilot program in the mid-1980s; large-scale development did not begin until the late 1980s, however, but was subsequently stalled because of declining market conditions for nahcolite used for flue gas desulfurization. In 1989, NaTec Ltd., a partnership between Industrial Resources Inc., and CRS Serrine, was formed to solution-mine nahcolite for sulfur dioxide scrubbing applications. The company experienced difficulties because of depressed markets. In 1992, North American Chemical Co. acquired 50% of NaTec's interest in the project, creating White River Nahcolite Minerals, Ltd. In 2003 Amerasia, Inc. partnered with The Sentient Group, an experienced international resource investment company, to acquire the company from IMC Global, the acquisition taking place through Amerasia's subsidiary, Natural Soda, Inc. This operation was later

sold and is currently being operated by Natural Soda, which produces sodium bicarbonate.

During the late 1990s American Soda LLC was founded to produce both sodium carbonate and sodium bicarbonate from this nahcolite resource. The operation continued under the ownership of American Soda until September 2003, when Solvay Chemicals purchased the assets. Solvay Chemicals continued to produce both soda ash (0.9 Mtp y capacity) and 90 ktp y of sodium bicarbonate until the summer of 2004, at which time the soda ash production facility was closed and the nahcolite feed shut down. Today the unit continues to produce sodium bicarbonate from soda ash from Green River.

The buried deposit in Green River Basin, Wyoming, is the largest trona resource in the world, covering more than 3,100 km² in southwest Wyoming. It is the result of the repeated evaporation of Lake Gosiute, a freshwater lake that formed in the Eocene epoch, and named by Clarence King in 1878 after a group of Native Americans who inhabited this area. The sodium and the carbonate constituents of trona owe their respective origins to the leaching of the extensive pyroxene-andesite volcanic ash horizons and the seasonal influxes of carbonate-rich sediments into the local depositional basin. Subsurface thermal springs also contributed a significant quantity of dissolved alkaline carbonates as well as sodium, calcium, silica, and bicarbonate ions. Trona can precipitate only in the presence of abundant carbon dioxide, which most likely was supplied from the atmosphere or the biogenic decay of Eocene plant and aquatic remains (Bradley and Eugster 1969). Leigh (1998) and Garrett (1998) contain additional information about the formation of trona in the Green River basin.

The Wilkins Peak Member (~ 410 m thick) of the Eocene Green River Formation contains 42 trona beds, 25 of which exceed 1.22 m in thickness and 175 km² of area. Eleven of these beds exceed 1.83 m in thickness. The beds dip slightly to the southwest, and are numbered from bottom to top. The center of trona deposition in the basin moved northward with time. Bed 1 was deposited the farthest to the south and Bed 25 about 40 km to the north. Halite, thin interbeds of sediments, and organic matter are the principal impurities within the trona horizons. The halite appears to occur most frequently in beds 5–18 and generally south and west of most of the producers. It has not been reported in beds 1, 4, 8, or any bed above 19. In the production areas, the chloride content is nearly always less than 0.5%. This is generally attributed to the mineral northupite, which occurs in thin shale stringers within the trona beds. The beds that have been mined (17, 19, 20, 24, and 25) contain 85%–95% trona, less than 15% insolubles, and less than 0.5% Cl, at depths ranging from approximately 240 to 520 m (Bed 25 to Bed 17). Beds 12 and 14 appear to contain minable trona directly beneath some of the current workings (Brown 1995; Wiig, Grundy, and Dyni 1995; Dyni 1997; Santini, unpublished data).

Many investigators have studied, described, and mapped the Green River trona deposit, and Wiig, Grundy, and Dyni (1995) did the most recent resource evaluation. Their resource estimates were derived using drill logs and geophysical information. The total resource is estimated to contain 127 Gt of trona in 22 beds greater than 1.22 m thick. Assuming that 1.8 t of trona yields about 1.0 t of soda ash, about 71 Gt of soda ash resources could be potentially obtained from the 76 Gt of bedded trona and the 51 Gt of interbedded or intermixed trona and halite that are in beds greater than 1.22 m thick. The resource occurs between 220 and 1,000 m below the surface in beds that range in area from 130 to 2,200 km² (Wiig, Grundy, and Dyni 1995).

Figure 2. Trona and soda ash operations in Green River Basin, Wyoming

Because this deposit is the most important geologic sequence of trona deposition currently known in the world, it will continue to supply soda ash for world consumption for centuries to come. Figure 2 shows a map of the Green River Basin with the approximate boundary of the known sodium leasing area and the location of the four soda ash producers (Solvay Chemicals, FMC Wyoming, OCI Chemical, and General Chemical).

The Yukon Flats basin of Alaska contains a series of shallow saline and freshwater lakes. Potash salts in the area have been known since 1929. In 1978, trona samples were identified in efflorescent crusts about 1 cm thick in certain lake margins and dry lake beds. The lakes trend in a northeasterly direction and occupy an area of about 240 by 48 km.

Although the sand hills area in northwestern Nebraska has numerous small lakes that contain primarily potassium carbonate, sodium carbonate occurs in some of the alkaline lakes. In Jess Lake, the sodium carbonate content is about 36% (Barbour 1916). Water draining through the sandy soils collects at the bowl of impervious mud bottoms.

Sodium carbonate also occurs in several lakes in south-central Oregon. Abert, Alkali, and Summer Lakes contain the most sodium carbonate of all the late-Pleistocene lakes in the region. Alkali Lake apparently was mined for a period beginning in 1955 by A.M. Matlock (*The Ore-Bin* 1955). Deposits of mixed salts formed in pot-holes, which were small brine pools where the brine was evaporated and the salts precipitated from the concentrated solution. The potholes resembled those formed in some Canadian lakes,

such as those in La St Chance Lake. Natron, sodium chloride, sodium sulfate, and some potassium salts were obtained from the deposit. Approximately 100 t had been mined by September 1955.

Trona, nahcolite, and other authigenic sodium minerals have been found while core drilling in the southwestern part of the Uinta Basin near Duchesne, Utah. The bedded deposit, with a maximum thickness of about 34 m, has an area of about 223 km² and lies about 73 to 128 m below the surface. Because the deposits are deep, solution mining would probably have to be used if this deposit were developed. Although current data indicates that this location contains less trona than in the Green River Basin in Wyoming and less nahcolite than in the Piceance Creek Basin in Colorado, the presence of sodium carbonate-bearing springs indicates the possibility of larger commercial deposits in the region (Dyni, Milton, and Cashion 1985).

Washington has several sodium carbonate deposits in lakes in the north-central portion of the state. The lakes with the highest sodium carbonate content are Mitchell Lake (5-ha area), Omak Lake (1,550-ha area), Soap Lake (350-ha area), and Salt Lake. These lakes contain varying concentrations of sodium salts, including natron, gaylussite, sodium chloride, and Glauber's salt. Carbonate Lake and Mitchell Lake produced commercial soda ash before World War II. Carbonate Lake was permanently flooded in 1950 when a dam was constructed as part of the Columbia irrigation project. The deposit no longer exists as a sodium carbonate resource (Bennett 1962).

Other sodium carbonate occurrences have been reported in Arizona, Montana, and North Dakota; detailed information regarding their geology, however, is scarce.

South America

Although South America has some of the world's largest salars (salt pans), it apparently lacks significant resources of natural sodium carbonate. Salars occur at high and low elevations, but most of the known surface salts are sulfate or sulfate-chloride varieties. Occurrences have been reported in the Los Andes Province of northwestern Argentina; in Bolivia; western Minas Gerais in Brazil; Chile; southern Peru; and Venezuela. The sodium carbonate deposits that occur in the area where Argentina, Brazil, and Chile meet are small and are considered economically insignificant (Catalano 1926; Cordini 1967).

Approximately eight sodium carbonate occurrences are found in the Santa Cruz Province of Argentina. Perhaps one of the best described deposits in the area is the Salina Juan Domingo play a lake, which averages 56.3% sodium carbonate and 8.3% sodium bicarbonate (Bernasconi and Cangioli 1982). Natron occurs on the surface, with trona and other carbonates found in the bottom muds. The dry lake bed may contain about 1.5 Mt of sodium carbonate equivalent. La Ernestina Lake in the Ultracan area and other nearby lakes such as Laguna el Carancho in La Pampa are reported to contain sodium carbonate (Cordini 1967).

Two alkaline lakes in Bolivia contain sodium carbonate: Cochi Laguna, 50 km south of Chiquana, which contains a trona and thermonatrite crust 6–10 cm thick, and Collpe Laguna, east of Salar de Chaivira. Collpe Laguna is a lake with an alkaline crust and contains subsurface sodium-carbonate-bearing brine in the bottom muds.

Several sal lakes occur in the Upper São Francisco area northeast of Brasília, Brazil. Some of the lakes contain soda ash crusts and shallow brine, with the average content ranging between 23% and 41% sodium carbonate. Sodium carbonate occurrences also are found in Urucuia, Carinhanha, Rio Correntes, and Rio Grande.

Trona and gaylussite occur in the surface crusts of the Lago de Laguinillus Valley of Venezuela. The salts average about 47% sodium carbonate. Between 50 and 80 t/y of crude trona (*urao*) have been produced by local residents. Another deposit is located at Urao Lagoon.

TECHNOLOGY

Exploration and Evaluation of Deposits

In formulating an exploration program for trona, it is essential to review the geologic characteristics of the deposits of the Green River Basin, Wyoming; Searles Lake, California; and Owens Lake, California. Vine and Santini (unpublished data) developed a list of factors favorable for the occurrence of buried and playa lake trona deposits:

- Green River Basin model (buried deposit)
 - Sedimentary basin containing nonmarine sediments
 - Lacustrine facies, including fine-grained, laminated sediments
 - Oil shale or similar organic-rich sediment of algal origin
 - Evaporite minerals, including shortite, pirssonite, gaylussite
 - Travertine algal mounds, bioherms, stromatolites, spring pots
 - Gypsum is absent or rare; other sulfates are minor
 - Alkaline spring or well waters; efflorescences in soil
 - Authigenic minerals, including magadiite, lacustrine clays, fluorite, potassium feldspar, zeolites
 - Altered volcanic ash, especially zeolitized
 - Evidence of solution, including collapse, brecciation
- Dyni (1998) discusses exploring for Green River type deposits.
- Searles Lake and Owens Lake model (playa lake deposit)
 - Closed basin with more than 2 km² of playa surface
 - Arid climate (high shorelines above present playa)
 - Organic-rich muds, odor of H₂S
 - Evaporite minerals or salts present
 - Authigenic minerals such as zeolites, fluorite, stevensite, hectorite, magadiite, opal
 - Travertine algal mounds, bioherms, stromatolites, spring pots
 - Gypsum absent or rare; other sulfates minor
 - Alkaline pH
 - Volcanic + crystalline terrain > sedimentary terrain in drainage basin
 - High geothermal gradient or thermal springs present

If a target justifies further exploration and evaluation, the next phase is a drilling program. Core drilling is the recommended method for both buried and playa lake-type deposits. Downhole geophysical logging methods, chemical analysis, x-ray diffraction, and so forth are also employed to evaluate both types of deposits.

In the Green River Basin, core drilling has been supplemented by downhole geophysics, including gamma ray, sonic, caliper, neutron, and rock density. The gamma-ray logs are used to determine trona thickness in conjunction with the lithologic logs.

X-ray diffraction is used to determine the mineralogy of the core samples. Typical chemical analyses include CO₃, HCO₃, Na, Ca, Mg, K, Cl, SO₄, and water insolubles. The trona content can be determined by titrating the water-leachable portion of core samples. Specifically, percent trona can be calculated from soluble Na₂CO₃, NaHCO₃, or Na₂O.

In the lake deposits of the Sevier Lake (brine-saturated evaporite), both core and brine samples are collected. After coring through an evaporite horizon, investigators collect brine samples by setting a packer and swabbing the hole. Drill core is subjected to x-ray diffraction and the same suite of chemical analyses described for Green River (i.e., CO_3 , HCO_3). In addition, acid insolubles and boron are determined at Sevier Lake (produces borate products also). The brine samples are subjected to the same suite of chemical analyses (minus insolubles) as the core samples. Specific gravity is also determined. Additional test work for selected core samples includes effective porosity and horizontal permeability determinations (Santini 1987). Downhole geophysical logging methods described for Green River are also used at Sevier Lake.

Mining

The Intermountain Chemical Co., a subsidiary of the Food Machinery Corp. (now FMC Corp.) began commercial mining of Wyoming trona in 1948. Because trona is similar to coal, except that trona is somewhat harder, early trona mining used some of the conventional coal-mining equipment. As mining technology improved over the next few decades, newer equipment—such as continuous miners—was adapted for trona mining in the early 1960s. Longwall mining, shortwall mining, and solution mining were introduced in the early 1980s. Dredging of sodium carbonate minerals from tailing ponds, another type of mining, began about 1985.

All Wyoming trona mines use room-and-pillar mining with multiple entry systems. Most have used one or more types of mining (conventional, continuous, longwall, shortwall, or solution). Two of the mines, FMC and Solvay, currently (2005) use the longwall method in addition to continuous mining. In addition, each company normally has several crews operating at different places in the mine during a production shift. Normally, room-and-pillar mining has an ore extraction efficiency rate of about 45% (the remaining 55% of ore remains as pillars for structural integrity). The pillars are part of the reserve base used for economic evaluation of ore reserves.

Extraction rates vary as does the depth of mining. Rooms are mined to form panels of varying dimensions, depending on the type of mining technology used. The heights and widths of the rooms and pillars depends on several factors, including the trona bed thickness, local conditions, and the depth of the particular mine. The deeper the mine, the greater the overburden pressure on the pillars, which may need to be larger to support the overlying strata. Usually pillar dimensions are greater in areas of long-term support, such as near main production and ventilation shafts and main entries. Removing the trona creates about 2 m of subsidence on the surface, although it is virtually unnoticeable. An average pillar measures about 21×24 m. The maze of interconnecting underground workings in each of the five Wyoming mines is extensive. FMC, for example, has more than 3,200 km of underground streets in its 39-km² area—more than the total length of the aboveground streets in San Francisco.

Conventional mining had been the primary method of mining trona ore but continuous mining is gradually replacing it. No conventional production is operating in the Green River basin today; currently, all production is by continuous miners, longwall, or solution.

In 1960, two European mining methods were introduced to Wyoming: the French, or pseudo-longwall, method and the English, or pseudo-shortwall, method. Both used a combination of borer miners and conventional equipment. Mining problems were reduced once extraction was limited to about 50%. Basically, two types of continuous miners are used: the drum-type and the borer-

type. The drum-type miner is used for short- to medium-life mine developments (10–18 years). Each mine operates on the advance and retreat methods; therefore, it is imperative that parts of the development remain in good condition for worker safety, ore haulage, and air ventilation requirements. Today either shuttle cars or continuous haulage units transport the ore cut by a continuous miner to the conveyor belt for haulage from the mine.

Boring machines mine long-term mainline entries (>30 year life) in some of the mines. The oval opening cut by these miners is more stable and has a longer life than the rectangular opening cut by a drum-type miner. The maximum single-pass boring machine opening is approximately 2.7 m high \times 4.9 m wide. Productivity has continued to increase as cutting-head designs have improved and haulage systems have been upgraded. Boring machines are now used for the short- and medium-life mine developments in conjunction with the drum-type miners.

Both FMC Wyoming Corp. and Solvay Chemicals, Inc., are the only natural soda ash producers that use longwall mining to augment their mining technology. Allied Chemical Co. (now known as General Chemical Corp.) was the first company to use longwall mining beginning in 1973 but abandoned the method after several years. FMC first installed longwall equipment in March 1981 but was hindered by the slow cutting rate of the equipment as well as slabbing and spalling problems with the trona. From July 1987 until May 1989, longwall mining temporarily ended with improvements in the machinery. These enhancements included slab retaining plates on the canopies of the shield supports that hold the trona face in place and a automatically retract as the shearer advances. Compared with continuous miners, longwall equipment is more expensive initially; the higher production and extraction rates, elimination of roof-bolting requirements, and greater safety for the miners, however, more than offset the expense. The longwall unit consists of an electric shearer with a lead and trail drum, an armored face conveyor, and face shields. The maximum panel width cut has increased to approximately 230 m with a maximum panel length of 2,900 m. The pillars left between panels are used for roof support. The roof of the mined-out areas ultimately collapses to relieve the stresses, creating massive piles of rubble called *gob*. The method also has an ore recovery rate of about 75% compared with the 45% for normal room-and-pillar mining with continuous mining equipment.

Roof bolting is the primary method of roof support used in the Green River mines. The majority of bolts used are rebar bolts that are fully grouted with an epoxy resin. A roof plate under the head of each bolt supports the immediate roof. Some bolts with mechanical expansion anchors are used where conditions are suitable. Normal roof bolt spacing is on 1.2-m intervals. It is common practice to leave some trona in the roof of the opening because the trona is more competent than the overlying shale and marlstone. The holes are drilled and the bolts are installed using a separate roof-bolting machine or bolters mounted on continuous miners.

After the ore has been cut, it must be transported to the production shaft where it is hoisted to the surface. Normal practice is to use 10- to 20-t-capacity shuttle cars (either diesel or electric) to move the mined rock to a feeder-breaker, which meters the ore onto a conveyor belt. A series of conveyor belts then delivers the ore to the production shaft. The trona may be crushed further before it leaves the mine. An alternative to shuttle cars is a continuous haulage unit that can use either conveyor belts or flexible steel conveyors. These units are more productive than shuttle cars because they eliminate the lost time that occurs as shuttle cars change places and haul to the belt conveyor.

The practice of solution mining reportedly was used more than 2,000 years ago in China to recover salt from deep subsurface

formations. FMC conducted a single-well solution-mining test in Wyoming in 1945 but encountered poor results and decided to pursue underground mining instead. Carl A. Bays endorsed the use of hydraulic fracturing used by the oil and gas industry to interconnect well pairs in the mid-1950s. Between 1955 and 1958 solution mining was conducted using this technique with moderate success. After years of further work and testing, FMC announced on January 14, 1981, its intention to construct a demonstration plant by mid-1981 using solution mining to recover trona from the deeper beds on state lease Section 36, T17N, R110W, which was about 26 km south of its existing refinery.

A well pair consists of an injection well and a production well located a few hundred meters apart. After the wells were drilled to about 655 m (bottom of Bed 1), steel casing was set into place and cemented to the well wall from the surface to below the bottom of the bed. The casing and cement were breached at the desired location of the fracture by using one of several techniques—cutting tools, jet notching, or explosive perforations. Several monitor wells were also drilled along the perimeter of the section to check if there were any excursions of the injection fluid. Water was slowly introduced through the casing to initiate hydraulic fracturing. Each injection well was pressurized to exceed the overburden lifting pressure plus the tensile strength of the trona horizon. Once this occurred, the horizon ruptured and the solution entered the bed and followed the path of least resistance. Ideally, the fracture should move horizontally toward the production well. Once communication was made with the production well, a solvent (caustic soda) was added to the water to completely dissolve the trona. If only water were used, the sodium bicarbonate contained in the trona would precipitate, deposit at the bottom of the solution-mined cavity, and cover the surface of the soluble trona, thereby reducing the quantity of sodium carbonate in solution and minimizing the utilization of the resource.

An extraction rate of 30% for trona solution mining was derived years ago based on information obtained from engineers engaged in solution mining of salt, potash, and nahcolite. Although there are no published reports to confirm or refute this estimate, it is conceivable that the extraction rate could be higher as more well pairs are established within an area and horizontal drilling is used to establish better communication and contact with the solvent within the trona beds.

FMC has been discharging tailings and spent solutions to its tailing ponds since about 1953. For about 50 years, sodium carbonate decahydrate crystals have been collecting on the bottom of these ponds. This represents a large, alternative resource available for recovery. Beginning about 1985, FMC used a dredge to extract about 160 kt of crystals annually from the 485-ha pond. The crystals are slurried, dewatered, melted, and processed into soda ash in the refinery. Other producers have similar ponds where sodium carbonate decahydrate has collected since the plants were built. At some time in the future they may collect and process these crystals as well. Because of environmental considerations and the cost of constructing and maintaining tailing ponds, three producers are injecting waste tailings underground. This minimizes future buildup of insoluble materials in the tailing ponds. In addition, two of the Wyoming soda ash producers are selling their spent purge liquors that contain several percent of dissolved sodium carbonate in solution. Local power utility companies purchase the liquors to scrub SO₂ from stack off-gas.

Feed for the Searles Lake operations comes from brine-bearing evaporate horizons in the lake. A system of wells (injection and production) and pipelines for each plant produces brine from the

horizons. Each system is designed to produce the best brine available for the plant it supplies. For some, solar ponds concentrate brine to increase plant production. For others, effluent is injected into an evaporite horizon (i.e., the Mixed Layer horizon) to manufacture brine by solution mining. Brackish water for plant use is obtained from a system of wells and pipelines on the north, west, and south sides of Searles Valley. The wells are completed in the alluvial sands and gravel beds that surround the saline body (Moulton and Santini 1995).

U.S. Borax Inc. operates a small mine at Owens Lake. The evaporite deposit is exposed at the surface. Trona is selectively mined with an excavator, stockpiled adjacent to areas of excavation (to debrine), and later spread out on the surface to air dry (Santini, unpublished data).

Nahcolite in the Piceance Creek Basin was solution mined for soda ash production beginning in 2000. The solution mining concept was based on work completed by Shell Oil Co. in the early 1970s (Hardy et al. 2003). The company conducted field testing for in situ recovery of oil from shale and discovered that nahcolite could be leached using high-temperature steam. The Shell method allows for the recovery of bedded nahcolite, in addition to nahcolite disseminated throughout the oil shale. American Soda later improved on this method, injecting pressurized water at high temperatures into wells drilled to approximately 670 m. Dissolution of the nahcolite produced vertical cavities.

Processing

Processing natural soda ash is significantly different than the chemical processes used to make synthetic soda ash. Processing trona ore and sodium-carbonate-bearing brines involves different mineral separation technologies, whereas manufacturing synthetic soda ash can be accomplished using one of several techniques.

Natural Soda Ash

Although trona ore averages approximately 90% pure sodium sesquicarbonate (with 10% accessory minerals), the ore must be further refined to produce a 99+% soda ash product. Sodium-carbonate-bearing brines contain a variety of other soluble minerals, including sodium sulfate, sodium chloride, potassium chloride, and borax, that must be physically and chemically removed from the brine to process the sodium carbonate content into refined soda ash.

Searles Lake Brine Process. A vast array of production wells covers the surface of Searles Lake to supply the Argus soda ash refinery with sodium-carbonate-bearing brine feedstock obtained from the Mixed Layer brine and the Lower Salt brine. The brines are pumped to the plant and are carbonated in carbonation towers with CO₂ gas obtained from calciner gas (from the conversion of soda ash from sodium bicarbonate) and from the monoethanolamine (MEA) towers that process the power plant's flue gases into purified CO₂ gas. The sodium carbonate in the brine is converted to sodium bicarbonate, which precipitates and then is collected, filtered, and calcined to light soda ash. This intermediate product is transferred to surge bins, which feed into one of three rotary bleaching units that operate at 427°C to remove residual organics. The material is concentrated and sent to sodium monohydrate crystallizers operating at 88°C that produce a larger-sized crystal. The product is screened, dewatered, washed in centrifuges, and dried and dehydrated in steam tube dryers at 260°C. The crystals are finally screened at 16 mesh and sent to storage. The final product is 99.7% sodium carbonate. The barren, or spent, solutions from the Mixed Layer brine and burkeite liquors are returned to the lake. The Lower Salt brine is treated separately at the Westend plant to

recover borax and sodium sulfate. Figure 3 shows a flow diagram of the Argus soda ash process.

Wyoming Trona Process. The two techniques to refine soda ash from trona ore are the sesquicarbonate process and the monohydrate process. Both use the same procedures but in different sequences. It takes approximately 1.8 t of trona ore to make 1.0 t of finished soda ash. The monohydrate method is the primary process used today to make soda ash. Figure 4 shows a flow diagram of both technologies.

FMC Corp. developed the monohydrate process in 1960. Although it patented and licensed the technology to other producers, FMC did not use the technique until 1972. In the monohydrate process, trona is crushed and calcined in rotary gas-fired calciners at 150°–300°C to remove water and carbon dioxide from the ore, which reduces the weight of the ore by 27%, leaving an impure product containing 85% sodium carbonate and 15% insolubles. The thermal decomposition of trona involves the following reaction:

The calcinate is dissolved with hot water and the clear, hot solution containing about 30% sodium carbonate by weight is sent to evaporative multiple-effect crystallizers or mechanical vapor recompression (MVR) crystallizers, where sodium carbonate monohydrate crystals ($\text{Na}_2\text{CO}_3 \cdot \text{H}_2\text{O}$) precipitate at 40°–100°C, which is below the transition temperature of monohydrate to anhydrous soda ash. The insoluble portion of the ore containing shale and shortite is collected by clarifiers, filtered, and then washed to recover any additional alkali before being piped in a slurry to tailing ponds or injected under ground in abandoned sections of the mine. Some companies pass the liquor through activated carbon beds before crystallization to remove trace organics solubilized from the oil shale so that the organics do not interfere with crystal growth rate and crystal habit in the crystallizers. The crystals are sent from the crystallizers to hydrocyclones and dewatered in centrifuges to between 2% and 6% free moisture. The centrifuge cake is conveyed to steam tube dryers where the crystals are dehydrated into anhydrous soda ash at 150°C, screened, and sent to storage or shipment. The final product made by the monohydrate process is dense soda ash with a bulk density of 0.99–1.04 g/cm³ and an average particle size of about 250 µm.

The sesquicarbonate process produces light to intermediate grades of soda ash crystals with a bulk density of about 0.89 g/cm³. The trona is crushed, dissolved in hot (95°C) mother liquor, clarified, filtered, and passed to cooling crystallizers, where crystals of sodium sesquicarbonate ($\text{Na}_2\text{CO}_3 \cdot \text{NaHCO}_3 \cdot 2\text{H}_2\text{O}$) precipitate. Activated carbon is added to filters to control the organics that interfere with crystal growth. The sodium sesquicarbonate is hydrocycloned, centrifuged, and calcined at 110°–175°C using gas or indirect steam heat. Dense soda ash can be made by calcining the sodium sesquicarbonate at 350°C.

Synthetic Soda Ash

Synthetic soda ash can be made by one of several chemical reactions that use common raw materials for feedstock, such as limestone, salt, and coal. Other technologies produce soda ash as a by-product of a process.

Leblanc Process. Nicolas Leblanc developed the Leblanc process in 1791 in the first effort to commercially synthesize soda ash. Common salt was combined with sulfuric acid to produce sodium sulfate and hydrochloric acid. The sodium sulfate was heated in a rotary furnace with coal and limestone (or charcoal and chalk) to produce a black ash, which contained sodium carbonate, calcium sulfide, and some unreacted coal. The mixture was leached with

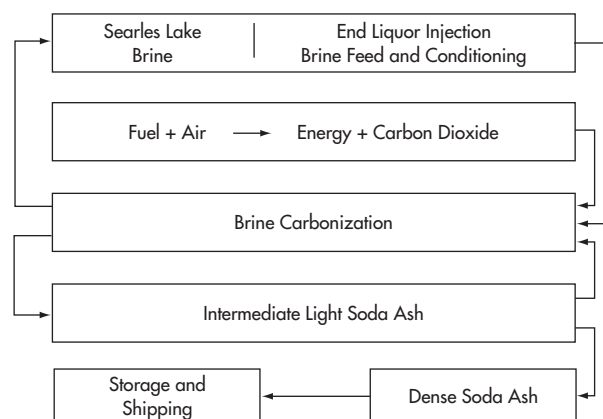

Figure 3. Argus soda ash process

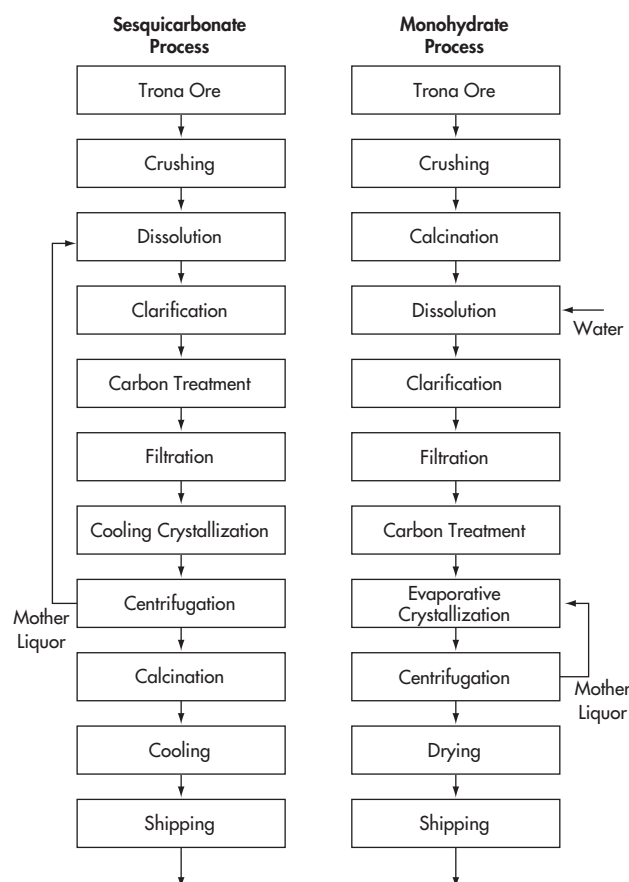

Figure 4. Two methods of producing soda ash from trona ore

cold water, which was evaporated or dried to obtain crystalline sodium carbonate. The chemical reaction was

The Leblanc process was used primarily in France and England. In about 1915, it was displaced by the Solvay ammonia-soda process; one plant in China, however, reportedly was producing

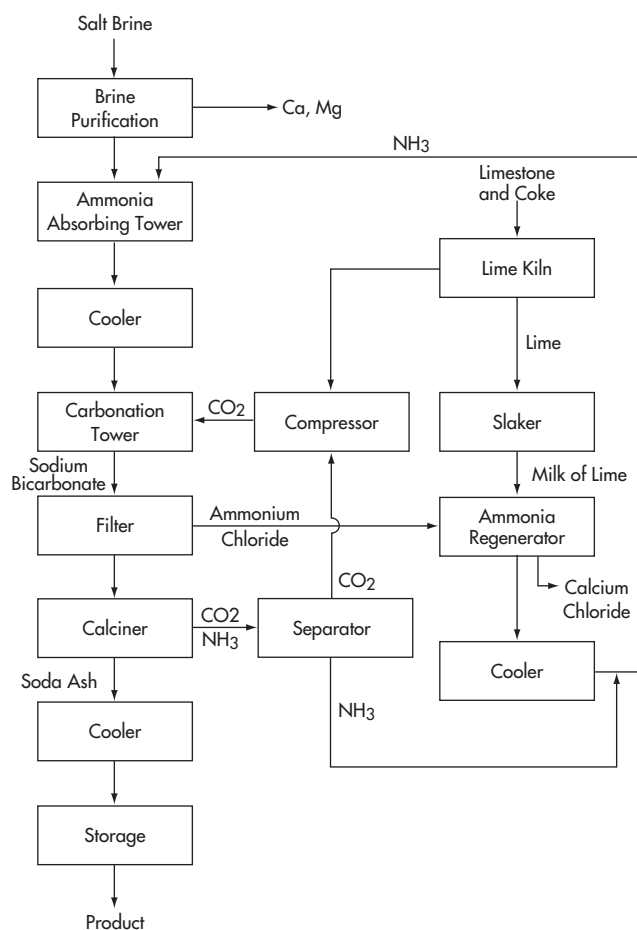

Figure 5. Flow diagram of the Solvay ammonia-soda process

about 250 tpy of soda ash as of 1950. The Leblanc technology was not used successfully in the United States except during a short period from July 1884 to January 1885 at a plant in Laramie, Wyoming.

Solvay Process. Also known as the ammonia-soda process, the Solvay process was developed by Alfred and Ernest Solvay in 1861 as an inexpensive way to manufacture soda ash on a large scale. Manufacturing 1.0 t of synthetic soda ash requires about 2.8 t of steam; 1.7 t of salt; 1.4 t of limestone; 0.6 t of coal for the boilers; and about 0.2 t of coal for the dryers. The process discharges approximately 1.7 t of waste products that include sodium chloride and calcium chloride. In the process, a sodium chloride brine is treated with milk of lime to remove magnesium ions and with soda ash to remove calcium ions. The brine is then saturated with ammonia, which acts as a carrier, and carbon dioxide gas in an absorption tower to produce ammonium bicarbonate, which reacts with the salt in solution to form sodium bicarbonate and ammonium chloride. The sodium bicarbonate precipitates, after which it is filtered and calcined at 175°–225°C to light soda ash (based on its bulk density of 0.51–0.62 g/cm³), and the gases produced are recycled back to the liquid phase. The solution containing ammonium chloride is reacted with milk of lime to recover the ammonia for reuse and to produce by-product calcium chloride for either sale or disposal. Limestone and coke are required to make the milk of lime. Dense soda ash (bulk density of 0.96–1.06 g/cm³) is made by hydrating

light soda ash to change the bulk density. The chemical reactions in the Solvay process are

The Solvay process is the dominant method used in the world today to manufacture synthetic soda ash. Approximately 70% of the total world output of soda ash is synthetic, the majority of which is from the Solvay process and the remainder from the ammonium chloride, New Asahi, and caustic carbonation processes. Figure 5 shows a flow diagram of the Solvay ammonia-soda process.

Electrolytic Process. Electrolytic soda ash is produced by introducing an electric current through a cell containing a saturated solution of sodium chloride. Sodium hydroxide forms at the cathode, and as carbon dioxide gas is passed through the solution around the cathode, sodium bicarbonate precipitates. The material is collected and dried to produce soda ash. In 1939, three electrolytic plants owned by the West Virginia Pulp and Paper Co. were in operation in Tyrone, Pennsylvania; Covington, Virginia; and Luke, Maryland. The plants also used the coproduct chlorine from the cells for bleaching applications.

Caustic Carbonation Process. Dow Chemical Co. operated the only caustic carbonation plant in the United States from 1955 to 1970 in Freeport, Texas. This plant, and a few others in the world, converted sodium hydroxide obtained as a coproduct from chlorine manufacture into soda ash. The sodium hydroxide in the electrolytic cell is treated with flue gas. The basic reaction is

Higher energy costs associated with the electrolytic process that produces both chlorine and caustic soda normally result in higher market prices for caustic soda compared with soda ash; therefore, this technique is not used extensively in the world.

Caprolactam Pyrolysis. This process involves pyrolyzing caprolactam residue to obtain a 95% sodium carbonate and 5% carbon product. A 40-tpd plant began production at Salamanca Guanajuato in 1989. The soda ash-carbon material was being sold to a pulp-and-paper operation that converted the soda ash to caustic soda. The small quantity of carbon in the soda ash reportedly was not a problem (Garrett 1992).

Ammonium Chloride (AC) Process. The Asahi Glass Co. of Japan developed the AC process in 1949 at the Kitakyushu Factory. It is essentially a modification of the conventional Solvay process. Because salt for synthetic soda ash manufacture must be imported, and therefore is expensive, a new technique was developed to improve the use of salt. In the Solvay process, about 70% of the sodium content in the salt is converted to soda ash with the remaining 30% and all of the chlorine discharged as waste. Only 28% (by weight) of imported salt was used to produce soda ash; the remaining 72% was lost as waste. The AC process uses more than 90% of the sodium from the salt. In the Solvay process, the ammonium

chloride produced is converted to ammonia and recycled; in the AC process, however, it is crystallized by cooling. Ammonium chloride is an excellent nitrogenous fertilizer used in Asia mainly for paddy rice; experimental applications, however, indicate it has beneficial uses for wheat, sugarcane, cotton, coconut and palm oil trees, bananas, and jute (Tsunashima and Nakaya 1982). Another difference between the Solvay and AC methods is that the AC method uses solid salt rather than salt brine as feedstock. In addition, the mother liquor is recycled to dissolve additional salt.

New Asahi (NA) Process. The NA process was developed in the early 1970s to improve on the AC and Solvay processes by reducing energy consumption, labor requirements, and equipment maintenance. The process has two variations that can be used, depending on the AC demand situation, and the NA monoproduction and coproduction processes. In the first variation, solid ammonium chloride reacts with a lime slurry to release the ammonia, which is recycled with a 25% calcium chloride solution (compared with a 10% solution in the Solvay process) discharged as waste or recovered for sale. In the other variation of the process, by-product solid ammonium chloride is produced by direct contact cooling crystallization when the facility has an ammonia plant. The NA coproduction process has lower production costs compared with the NA monoproduction technique.

Akzo Process. Akzo Zout Chemie of the Netherlands developed a process to make vinyl chloride and soda ash from salt using an amine-solvent system catalyzed by a copper-iodide mixture (Akzo N.V. 1981). Van Andel (1983) indicated that the method was an alternative to salt electrolysis, direct ethylene chlorination, and oxychlorination techniques. It produces soda ash rather than caustic soda and uses steam instead of electricity, reducing total energy consumption about one half that of the conventional process.

Ormiston Mining Process. Although Ormiston Mining and Smelting of Canada developed this process mainly to produce sodium hydroxide, it can be altered to produce soda ash. The method involves electrolysis of a sodium sulfate solution in an electrolytic cell that generates sulfuric acid. Ammonia is added to neutralize the acid and the process ultimately produces sodium hydroxide and ammonium sulfate. The caustic soda can be reacted with lime and converted to soda ash. Although the operating economics appear to be cost-prohibitive, some nations without soda ash resources but with abundant sodium sulfate deposits may find this process promising (Thompson and Genders 1992).

Hüls Process. The Hüls process produces soda ash and hydrochloric acid from salt using an amine-solvent system (Rauh 1991). The technique was developed by Chemische Werke Hüls AG, which was awarded a U.S. patent in 1982. The by-product hydrochloric acid may be easier sold than other by-product chemicals recovered from other processes, depending on market conditions.

END USES

Soda ash obtained from either natural or synthetic production processes serves a variety of end-use markets. The markets in developed nations are mature and are not expected to grow appreciably but will generally parallel the population growth rates of those nations. In developing countries, where the glass, chemical, and industrial sectors are emerging, consumption is expected to grow more significantly as the demand for consumer products increases.

Soda ash has been used in glass and soap manufacture for more than 5,500 years and these continue to be important end uses today. Older uses for soda ash, such as embalming the dead, treating colic pains, and making bread, gave way to newer uses in the 20th century, such as pH control in swimming pools, flue gas desulfurization for cleaner air, and glass fiber insulation for homes. Although sur-

rounded every day by many consumer products that contain soda ash, most people are unfamiliar with what soda ash really is. Based on reported industry sales in 2004, the manufacture of glass products represented about 50% of domestic soda ash consumption, with the glass container and beverage sector as 49% of this end use; flat glass, 36%; fiber glass, 9%; and specialty glass, 6% (i.e., glass tumblers, medicine bottles, incandescent bulbs, etc.). The other end uses were chemicals (mainly sodium bicarbonate, sodium chromates, sodium phosphates, and sodium silicates), 26%; soaps and detergents, 11%; distributors (which buy soda ash directly from the producers and resell it to various downstream consumers), 5%; miscellaneous uses, 4%; flue gas desulfurization, 2%; and pulp-and-paper and water treatment, 1% each.

Glass

The glass industry is the largest consumer of soda ash, especially the glass-container sector. Soda ash is a source of sodium oxide that is used as a fluxing agent in container, flat, fiber, and specialty glass manufacture to reduce the temperature at which the raw materials melt. Soda ash decomposes into sodium oxide and carbon dioxide, which rises through the glass melt and helps mix the ingredients.

Soda-rich glass is softer than other more refractory types of glass; therefore, forming is easier. The quantity of soda ash added to glass batches varies with the type of glass being manufactured and the percentage of recycled glass (also known as *cullet*) being used. Glass containers, for example, may require more than 180 kg of dense soda ash for every 450 kg of silica sand. A typical batch for clear glass containers may consist of 155 kg soda ash; 172 kg limestone; 145 kg feldspar; and 5 kg sodium sulfate. Flat-glass batches require about 115 kg of soda ash per 450 kg of silica sand used. The growing nationwide effort to recycle glass has benefited many of the domestic glass-container manufacturers because cullet substitutes for part of the raw material requirements in a glass batch. Cullet also melts at lower temperatures (about 20%–25% lower), thereby reducing glass-production costs. The increased use of cullet has conversely affected soda ash consumption. The U.S. soda ash consumption in the glass-container industry has also declined because of increased use of polyethylene terephthalate (PET) plastic containers.

Chemicals

The inorganic chemicals industry is the second largest user of soda ash, comprising 26% of total domestic demand. Although many sodium-based compounds are indirectly produced from soda ash, the primary chemicals that are directly manufactured from soda ash feedstock are discussed in the following subsections.

Sodium Bicarbonate

Sodium bicarbonate, or baking soda, is manufactured by percolating CO₂ gas through a carbonation tower containing a saturated soda ash solution. The sodium bicarbonate precipitate is collected, filtered, centrifuged, dried, screened, and packaged. Approximately 0.68 t of soda ash is required to make 1 t of sodium bicarbonate. The major uses of sodium bicarbonate are household consumer products, animal feed, foods for human consumption, baking products, beverages, plastics, chemicals, pharmaceuticals, personal-care products, fire extinguishers, soaps and detergents, flue gas scrubbing, and other miscellaneous end uses. Five producers operating six plants have a combined annual production capacity of about 708 kt. Two of the companies are also soda ash producers.

Sodium Hydroxide (Caustic Soda)

Caustic soda is mainly produced as a coproduct with chlorine gas in the electrolysis of salt brine in mercury, diaphragm, or membrane

cells. Nonelectrolytic caustic soda, however, also known as *chemical caustic soda*, has been produced in the last decade by several of the Green River soda ash producers. The lime-soda process was the primary method of caustic soda manufacture at the beginning of the 20th century before the electrolytic process gained favor. Chemical caustic soda is produced by the following reaction:

The lime is slaked—CaO converted to Ca(OH)₂—and added to 1.33 t of dissolved soda ash to produce 1.0 t of chemical caustic soda. Calcium carbonate is precipitated from the reaction, calcined back to lime, and recycled.

Sodium Sesquicarbonate

Sodium sesquicarbonate is a hydrated compound containing soda ash and sodium bicarbonate. Trona ore is first crushed and dissolved to separate the insoluble impurities. The sodium compounds in solution are then clarified, filtered, crystallized, centrifuged, calcined, and recovered as long, needle-shaped, monoclinic crystals of sodium sesquicarbonate. FMC Wyoming Corp. has a 50-ktpy sodium sesquicarbonate facility in Wyoming that sells mainly to the detergent industry.

Sodium Chromates

Chrome ore is roasted with soda ash in a rotary kiln to produce sodium chromate or sodium bichromate; these are used to produce other chromium compounds such as chromic acid and chromic sulfate. The chemical reaction is

For every ton of sodium bichromate produced, 0.79 t of soda ash is required. The end uses of sodium bichromate are chromic acid, chromium oxide, leather tanning, pigments, wood preservatives, drilling mud additives, and other uses (metal finishing, water treatment, textiles, catalysts).

Sodium Phosphates

The phosphate chemicals, and the corresponding quantity of soda ash required to make 1 st of the chemical, are as follows: sodium tripolyphosphate (Na₅P₃O₁₀), 0.76 st; mono sodium phosphate (NaH₂PO₄), 0.45 st; disodium phosphate (Na₂HPO₄), 0.747 st; trisodium phosphate (Na₃PO₄), 0.68 st; sodium metaphosphate (NaPO₃), 0.557 st; sodium acid pyrophosphate (Na₂H₂P₂O₇), 0.478 st; and tetrasodium pyrophosphate (Na₄P₂O₇), 0.84 st. The sodium phosphates have exceptional cleaning properties, especially sodium tripolyphosphate, and are also used in baking powder, carbonated beverages, milk products, dental materials, fire-resistant products, metal surface treatments, and water treatments.

Sodium Silicates

Sodium silicate is produced from silica sand and soda ash in a process similar to glass manufacture except that the sodium silicates are water soluble and glass is not. The two raw materials are melted at 2,450°C in an open-hearth furnace. The melt is withdrawn, cooled, crushed, and dissolved under pressure with steam. The three types of sodium silicate s, and the corresponding quantity of soda ash needed to produce 1 st of the chemical are sodium orthosilicate (0.8 st); sodium metasilicate pentahydrate (0.33 st); and water glass (0.37 st). Sodium silicates are used in soaps and detergents; silica-type catalysts and gels; pigments; paper adhesives; water, paper, and ore treatment; and other miscellaneous end uses.

Other Sodium Chemicals

Many other sodium-based chemicals are derived from soda ash. Sodium aluminate, sodium cyanide, sodium fluoride, and sodium sulfite are just a few examples.

Soaps and Detergents

The third largest end use of soda ash is in soap and detergent manufacture, accounting for 11% of total domestic consumption. Soda ash is used directly and indirectly in this sector with different functions. First, soda ash is added directly to different detergent formulations to serve as an agglomerating aid, surfactant carrier, and source of alkalinity. Second, soda ash is the feedstock to make other sodium-based chemicals known as *builders*. Builders are agents that enhance the cleaning action in the liquid washload by tying up the calcium and magnesium ions to improve surfactant activity. The builders include sodium tripolyphosphate (which is an excellent builder but contributes to the environmental problem of eutrophication), sodium silicates, and synthetic zeolites. One or a combination of these is used in various detergent formulations. Lastly, soda ash is used to soften laundry water.

The end-use data presented pertain to the direct use of soda ash in soap and detergent manufacture; the quantity of soda ash used to produce other sodium chemicals used in formulations are included in the chemicals sector, which is the primary, first-tier consumer. Soda ash is used in powdered home and industrial detergents but not in the newer liquid detergent formulations. Many states have legislation to restrict or ban the use of phosphatic detergents because of environmental considerations; therefore, detergent companies have modified product formulations to accommodate regional market restrictions. As a result, national sodium tripolyphosphate consumption has been decreasing, thereby reducing soda ash usage. To compensate for the decline, additional soda ash has been added to detergents as alternate medium-strength builders, such as in synthetic zeolites and in sodium silicates. Despite the growth of liquid detergent use, the net effect is that soda ash consumption in the soap and detergent sector remains strong.

Flue Gas Desulfurization

Flue gas desulfurization reduces SO₂ emissions in stack gases from the burning of fuel. Soda ash and other soda ash-based compounds such as sodium bicarbonate and sodium sesquicarbonate are very effective dry sorbents of sulfur and nitrogen compounds. The reaction is as follows:

Compared to calcium-based compounds such as lime and limestone, scrubbing reagents based on soda ash have been proven to be more effective scrubbers because of their greater surface area, which enhances the reaction with sulfur and nitrogen. Soda ash, however, remains more expensive and geographically restrictive than calcium materials. Most of the power plants that burn high-sulfur coal are east of the Mississippi River, where there are plentiful limestone quarries that can be mined more economically and the product transported shorter distances than soda ash produced in the West. Therefore, the quantity of soda ash sold for this end use is restrictive because of the economic advantages of lime and limestone. Some soda ash, however, is blended with lime for use in the dual-alkali process. The flue gas desulfurization market is 2% of total domestic soda ash sales.

Distributors

Distributors offer a variety of services to many soda ash consumers that may not be available from a soda ash producer directly, such as

buying in bags, small volumes, or on an infrequent basis. Soda ash sold to distributors for resale comprised 5% of domestic reported consumption in 2004.

Pulp and Paper

Soda ash is used in pulp digestion and bleaching operations and in water treatment and paper-coating formulations. Its main use is in making the sodium sulfite buffer solution used in the neutral sulfite pulp-manufacturing process, in which the soda ash neutralizes the corrosive effects of the recovered black liquor. Although many pulp mills had used caustic soda because of its high sodium oxide content and its strong alkalinity, high prices and supply shortages of caustic soda prompted several mills to switch to soda ash, which was less expensive and more available. The total market represented about 1% of U.S. soda ash sales in 2004.

Water Treatment

Soda ash is used to chemically alter the pH of municipal and industrial water supplies and as a precipitant to remove impurities in brine and industrial process water. In the basic water treatment process, soda ash is added to adjust acidity or alkalinity. Generally, it is added to acidic water to raise the pH and reduce the corrosivity of the water and the accumulation of mineral scale, thereby extending the life of metal pipes and equipment. One example of this application is in swimming pool chemicals where soda ash is added to adjust the pH of the water.

As a precipitant, soda ash removes calcium and magnesium ions and other contaminants from water, which decreases the hardness of water. Most chlorine and caustic soda manufacturers pretreat the sodium-chloride-rich brine feedstock with soda ash to remove any calcium and magnesium impurities, thereby improving feedstock composition and product quality.

Since 1987, when the U.S. Bureau of Mines began collecting reported soda ash consumption data, a certain quantity of soda ash equivalent contained in purge liquors, soda liquors, and mine waters has been sold to coal-fired power plants for process water treatment. These data are included under the water treatment category rather than under flue gas desulfurization.

Another unique soda ash application in water treatment involves treating surface waters (e.g., lakes and rivers) contaminated from acid rain or natural causes. Although soda ash is a more expensive alkaline compared with less expensive calcium-based reagents such as limestone, it reportedly is more effective than lime in neutralizing the effects of acidification. The concept has been conducted in lakes in Sweden and New York with positive results; the practice has been criticized, however, for merely treating the result of acid rain rather than attempting to prevent the spread of pollution from the source, which would involve flue gas desulfurization. The total quantity of soda ash used for all water treatment applications is about 1% of total soda ash demand.

Miscellaneous Uses

Although soda ash is used in several minor applications, specific end-use data are unavailable; the total category, however, is 4% of domestic reported consumption. The uses include agriculture, brine treatment, corn syrup manufacture, drilling mud additives, dyes and pigments, enamels, food processing, leather tanning, metal refining, perfume, pharmaceuticals, and textiles.

ECONOMIC FACTORS

Transportation and Packaging

Soda ash is packaged in 23–46 kg paper bags and 1-t supersacks. Large quantities are shipped in bulk, often using unit trains (~100-t

railcars). Producers use dedicated port facilities and chartered vessels that allow soda ash, a low-unit-value product, to be exported around the world. Smaller shipments of both bulk and bagged soda ash are to domestic customers.

Prices

For three quarters of the 20th century, the synthetic soda ash industry with several nationwide plants established the lead for setting the soda ash selling price, leaving the smaller natural soda ash industry to follow by paralleling any price movement made by the former. Rising fuel costs after the 1973 energy crisis, coupled with pollution-abatement equipment required by environmental legislation, adversely affected the synthetic industry more than the natural operators, thereby creating a two-tier sales price—one for natural soda ash and another for synthetic soda ash.

The posted list price of natural soda ash differs from the value that is reported to and by USGS annually. The value may or may not correspond to the published list price for the commodity. The values that tend to be synonymous with the average market price are the combined total revenue of Wyoming and California natural bulk, dense soda ash sold on an f.o.b. (free-on-board) basis at list prices, spot prices, discount, long-term contracts, and for export, divided by the aggregate quantity of soda ash sold. Bagging, handling, and insurance costs are not included. The average annual value for bulk, dense soda ash, f.o.b. Green River, Wyoming; Searles Valley, California; and Parachute, Colorado (now dormant); was \$70.27/t in 2004. On July 1, 2004, the list price for Wyoming bulk dense soda ash was raised from ~\$116/t to \$139/t. The California price for the comparable product was increased from ~\$144/t to \$150/t.

Foreign Trade

Before the startup of synthetic soda ash manufacturing in the United States in 1884, and apart from limited natural soda ash production in the West, imported soda ash supplied most domestic supply requirements for the glass and detergent industries. As domestic soda ash production capacity expanded, the United States rose from being import dependent to a net exporting nation.

Imports

England had been a major source of soda ash imports in the late 19th and into the 20th century. Synthetic soda ash plants were built in Canada and Mexico primarily to satisfy those countries' requirements; because of their close geographic location, however, these nations began trading with the United States to solve supply shortages or to provide alternate soda ash grades. The Solvay plant in Amherstburg, Ontario, has now been closed, and only one facility remains in Mexico. Imports of soda ash in 2004 increased by 20% to 6,000 t from 2003. In 2004, about 41% of imports were from the United Kingdom and 37% from Mexico. The remainder was from Belgium, Bulgaria, China, Germany, India, Japan, Taiwan, and Turkey.

Exports

U.S. soda ash exports have grown significantly in the last two decades because of increasing world demand, favorable currency exchange rates, lifting or easement in foreign tariffs and embargoes, and synthetic soda ash plant closures. Another important factor has been the creation of the domestic export association known as the American Natural Soda Ash Corporation (ANSAC), which was reorganized in 1983 from the Soda Ash Export Trading Association assembled in 1982. ANSAC has been very successful in raising export sales by consolidating the efforts of four individual U.S.

soda ash producers in the world market. In 1981, before the creation of ANSAC, exports were only 13% of U.S. production, but by 2004 it had risen to more than 43% of total production. Exports of soda ash in 2004 were 4.67 Mt. In 2004, U.S. exports to 44 countries, on a regional basis, were as follows: Asia, 36%; North and South America, 22% each; Europe, 11%; the Middle East, 4%; Oceania, 3%; Central America and Africa, 1% each; and the Caribbean, less than 1%.

FUTURE OUTLOOK

The outlook for U.S. soda ash for the next 5 years is optimistic, despite competition from Chinese soda ash producers (Kostick 2004). According to the USGS, the market for domestic soda ash is expected to grow by about 0.5% per year, and the world demand is forecasted to range from 2% to 2.5% per year for the next several years. Asia and South America are the two areas that will continue to have increased soda ash consumption in the near future. In contrast, ANSAC estimates world demand for soda ash will grow about 4%–4.2% per year for the next few years.

ACKNOWLEDGMENTS

The authors thank Dennis Kostick for his well-written chapter in the 6th edition of *Industrial Minerals and Rocks*; this work is not a complete rewrite, but rather an update of Kostick's chapter (with selected sections that are new). The authors thank all of the Solvay Chemicals personnel who provided input for this chapter. James Barker is thanked for his assistance in completing the chapter.

Sodium Sulfate Resources

George S. Austin and Birney Humphrey

INTRODUCTION

Sodium sulfate is an important industrial chemical. As recently as 25 years ago, it was produced and consumed in the United States in quantities exceeding 1 Mtp y. Since then, both its production and use have declined; approximately half the production, however, still comes from natural sources. Figure 1 illustrates the history of production of natural sodium sulfate (up to 1997) and manufactured sodium sulfate in the United States. Production of natural sodium sulfate from various types of deposits is the main source of this chemical in Canada, China, Mexico, and Spain, and probably in Argentina, Chile, Iran, Spain, and the Russian republics.

In the United States, more than one half of the total output is a by-product of various manufacturing processes or products including ascorbic acid, battery reclamation, cellulose, rayon, and silica pigments (Kostick 2005). In addition, there is sizable production of sodium sulfate from other chemicals (primarily salt and sulfuric acid), called “salt cake” (Garrett 2001). The U.S. Geological Survey (USGS) does not separate natural sodium sulfate from synthetic sodium sulfate in reporting production (Kostick 2005).

MINERALOGY AND PHYSICAL PROPERTIES

Sodium sulfate is widespread in occurrence and is a common constituent of many mineral waters and seawater. Atmospheric precipitation contains sulfate; it is one of the major dissolved constituents of rain and snow (Davis and De Wiest 1966). Many of the saline lakes throughout the world contain varying amounts of sodium sulfate. Because sodium is usually the dominant cation, some make an anionic distinction, referring to lakes containing predominantly sulfate as bitter lakes and those containing predominantly carbonate as alkali or soda lakes (Bateman 1950). Sodium sulfate in its natural form is found in two principal minerals, mirabilite and thenardite. Mirabilite, the hydrous form, is commonly called Glauber’s salt. It was discovered by the German chemist J.R. Glauber (1603–1668), who derived its name from the Latin, *sal mirabile*, meaning wonderful salt. Thenardite, the anhydrous variety, was named for the French chemist Louis Jacques Thenard (1777–1857) of the University of Paris (Mitchell 1979). The largest quantities occur in the form of mirabilite. Sodium sulfate is found in varying degrees of purity, from theoretically pure efflorescent crystals of mirabilite to combinations and admixtures of other salts and impurities. It is a common constituent of some brines; from this source, much is extracted commercially.

Adapted from McIlveen and Cheek 1994.

Figure 1. Sodium sulfate production in the United States, manufactured and natural until 1997. Only total sodium sulfate production has been published since 1997.

Sodium sulfate also is found in compounds such as the minerals glauberite, the double-salt of anhydrous sodium and calcium sulfate; bloedite, the hydrous double-salt of sodium sulfate and magnesium sulfate; and burkeite, the anhydrous double-salt of sodium carbonate and sodium sulfate.

More than 40 minerals contain sodium sulfate in varying proportions; many are of special interest because of their frequent occurrence.

Table 1 lists some sodium sulfate bearing minerals. The reader is referred to other publications (Grabau 1920; Cole 1926; Dana 1932; Dietrich 1969) for descriptions of these minerals. Only mirabilite and the nardite will be described in this chapter. Mirabilite, $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$, contains 55.9% water of crystallization. It is noted for its efflorescence or spontaneous loss of water. On dehydration, it changes to the anhydrous form, Na_2SO_4 . Mirabilite is an opaque to colorless, water-soluble mineral that tastes first cool, then slightly bitter. It has a specific gravity of 1.48. It frequently forms as efflorescent, needlelike monoclinic crystals but generally is found in the massive form.

Thenardite, the anhydrous mineral Na_2SO_4 , contains 43.68% Na_2O and 56.32% SO_3 . It ranges from colorless to white and may be tinted shades of gray or brown. It is a water-soluble mineral with a

Mineral	Composition	% Na ₂ SO ₄
Thenardite (anhydrous)*	Na ₂ SO ₄	100
Hanksite	9Na ₂ SO ₄ •2Na ₂ CO ₃ •KCl	81.7
D'ansite	9Na ₂ SO ₄ •MgSO ₄ •3NaCl	81.2
Leontite	(Na,NH ₄ ,K) ₂ SO ₄ •2H ₂ O	<79.8
Vanthoffite	3Na ₂ SO ₄ •MgSO ₄	78
Hectorfloresite	4Na ₂ SO ₄ •NaClO ₃	74.1
Sulphohalite	2Na ₂ SO ₄ •NaCl•NaF	73.9
Burkeite	Na ₆ (SO ₄) ₂ (CO ₃)	72.8
Eugsterite (Fritzsche's salt)	2Na ₂ SO ₄ •CaSO ₄ •2H ₂ O	62.3
Darapskite Na	NO ₃ •Na ₂ SO ₄ •H ₂ O	58.0
Hydro-glauberite	5Na ₂ SO ₄ •3CaSO ₄ •6H ₂ O	57.9
Glauberite	Na ₂ SO ₄ •CaSO ₄	51.1
Loeweite	MgSO ₄ •Na ₂ SO ₄ •2½H ₂ O	46.2
Ferrinatrite	3Na ₂ SO ₄ Fe ₂ (SO ₄) ₃ •6H ₂ O	45.6
Mirabilite (Glauber's salt)	Na ₂ SO ₄ •10H ₂ O	44.1
Bleodite (astrakanite)	MgSO ₄ •Na ₂ SO ₄ •H ₂ O	42.5
Kroehnkite	CuSO ₄ •Na ₂ SO ₄ •2H ₂ O	42.1
Nickelbleodite	Na ₂ Ni(SO ₄) ₂ •4H ₂ O	40.3
Sideronatrite	Na ₂ Fe(SO ₄) ₂ (OH)•3H ₂ O	38.9
Caracolite	Pb(OH)Cl•Na ₂ SO ₄	35.4
Palmierite	(K,Na) ₂ Pb(SO ₄) ₂	<31.9
Tychite	2MgCO ₃ •2Na ₂ CO ₃ •Na ₂ SO ₄	27.2
Aphthalite (glaserite)	(K,Na) ₃ Na(SO ₄) ₂	21–38
Tamarugite	Na ₂ SO ₄ •Al ₂ (SO ₄) ₃ •12H ₂ O	20.3
Natrochalcite	Cu ₄ (OH) ₂ (SO ₄) ₃ •Na ₂ SO ₄ •2H ₂ O	18.8
Almeriite	Na ₂ SO ₄ •Al ₂ (SO ₄) ₃ •5Al(OH) ₃ •H ₂ O	15.9
Mendozite (soda alum)	Na ₂ SO ₄ •Al ₂ (SO ₄) ₃ •24H ₂ O	15.5
Natrojarosite	Na ₂ Fe ₆ (OH) ₁₂ (SO ₄) ₄	14.7
Noselite	3Na ₂ Al ₂ Si ₂ O ₈ •Na ₂ SO ₄	14.3
Slavikite	(Na,K) ₂ SO ₄ •Fe ₁₀ (OH) ₆ (SO ₄) ₁₂ •63H ₂ O	<4.6

* Salt cake is anhydrous sodium sulfate with a purity lower than 98%.

slightly salty taste. Its specific gravity (2.67) and hardness (2.5 to 3) exceed those of mirabilite. It commonly occurs in the massive form without visible crystals. Its crystals are frequently tabular pyramids of the orthorhombic system.

Sodium sulfate also occurs as a heptahydrate, containing seven molecules of water, but this is unstable and has not been found in the natural environment.

The solubility of sodium sulfate has an important effect on the crystallization of the salt in nature, as well as in its production. Its solubility in water generally increases as a nonlinear function of temperature. Below 1.2°C, ice and mirabilite form. As the temperature increases above 0°C, increasing amounts of sodium sulfate become soluble. At 32.4°C, a transition point on the solubility curve is reached as the decahydrate melts in its own water of crystallization and the anhydrous form crystallizes. With increasing temperatures, solubility decreases somewhat. The presence of other dissolved salts changes the transition temperature and solubility characteristics of sodium sulfate.

CLASSIFICATION OF DEPOSITS

Essentially all commercial deposits of sodium sulfate resulted from accumulation and evaporation of surface water and groundwater in basins with interior drainage called *playas*. They are found in arid to semiarid regions. Thus these deposits fall within the broad classification of evaporites. They can be further classified into two categories: (1) those occurring as crystalline beds of mirabilite or glauberite and/or brines within or underlying playalakes; and (2) those found as buried beds of thenardite, glauberite, and associated minerals. The first category includes the principal deposits of the world. Notable among these are the lake deposits of western Canada; Great Salt Lake, Utah; the vast mirabilite-glauberite deposits of the Kara Bogaz Gulf on the eastern shore of the Caspian Sea; and the brine deposits of the western United States and Mexico. These require pumping, dredging, or reservoiring for exploitation.

Commercial deposits of the second category are relatively rare. Deposits of thenardite and glauberite are being mined in Spain, and thenardite was mined at Camp Verde, Arizona, and at Rhodes Marsh near Mina, Nevada. Conventional mining techniques are used for extraction.

ORIGIN OF SODIUM SULFATE DEPOSITS

Evaporation of surface waters, with consequent concentration of salts, is the principal agent in the formation of alkali and bitter lakes from which sodium sulfate and other salts are extracted. Because of the great difference in composition between sea water salts and those of playalake deposits, it is generally accepted that the se deposits are recent accumulations from nonmarine sources.

The brines of playalake deposits are more diverse in composition than seawater because each deposit contains soluble salts from discrete sources within its drainage area. The salinity of the brines is much greater because of the high rates of evaporation characteristic in arid interior basins where the deposits occur.

The evolution of brine and subsequent precipitation of minerals involve complex geochemical factors. These include the weathering of solutes from the watershed, their transport to the playa basin, and their evaporative concentration. Jones (1966) pointed out the importance of lithology and weathering processes to the dominant anion in playalakes of the western United States. Krauskopf (1967) discussed the fate of various elements and radicals during transport and the eventual arrival of sodium as the dominant cation, and either sulfate or chlorides as the chief anion. McIlveen and Cheek (1994) reported that in 1970 Hardie and Eugster discussed the evolution of dilute waters in closed basins, placing them into four groups: Group A (Na-CO₃-SO₄-Cl brines), Group B (Na₂SO₄-NaCl brines), Group C (Na-Mg-Ca-Cl brines), and Group D (Na-Mg-SO₄-Cl brines). The precipitations of calcite, sepiolite, and gypsum are important points of bifurcation during the evolutionary process.

In nature, two processes—evaporation and cooling—cause the deposition of sodium sulfate. Evaporation decreases the volume of water, and cooling decreases the solubility of the salt. Below the freezing point of water, ice decreases the available water for solution and the solubility of sodium sulfate minerals, causing mirabilite to form. This natural phenomenon accounts for the accumulation of intermittent beds of crystalline sodium sulfate in the bitter lakes of Canada, Russia, and the United States from which sodium sulfate may be harvested during the winter. Crystallization from cooling also results from day and night temperature changes, particularly at high elevations where these changes can be extreme.

In warmer climates, evaporation is the principal agent of precipitation of sodium sulfate. In those climates, natural cooling is not employed in the production of sodium sulfate, but concentrated

brines are pumped to the surface and cooled by refrigeration to yield mirabilite crystals.

Most sodium sulfate deposits of commercial significance contain permanent crystalline beds and brines at or near the surface. The crystalline beds can range in thickness from a few millimeters to several meters. They usually are interstratified with other salts, clays, silts, and organic matter. The impervious clays and silts help preserve a portion of the intermittent beds from redissolving. Brines generally occur with in crystal beds, but in some deposits crystal beds are lacking.

In most deposits, sodium sulfate predominates, with sodium and magnesium chlorides, magnesium sulfates, and carbonates also present. In more complex deposits, concentrations of potassium chloride and borates can be appreciable, depending on the location of the deposit in relation to the source of soluble salts.

The origin of sodium sulfate deposits has prompted many theories. Variations in these theories mainly concern the source of alkalic salts that make up the deposits. Other factors considered are the origin of the basin and the agent of transportation and deposition of the sodium sulfate (Ruffel 1970).

Early theories generally attributed the source of the salts to decomposition of granitic rocks. It was assumed that the feldspars in granites yielded soluble salts that were transported by surface waters, and that pyrite and other sulfides in these rocks were oxidized to sulfuric acid, which immediately dissolved some of the basic oxides to produce soluble sulfates (Wells 1923).

Following an extensive study of the deposits of western Canada, L.H. Cole (1926) considered four possible sources of the sodium sulfate: (1) underlying sands and shales, which contain small amounts of alkalis, and interbedded volcanic-ash beds, which contain an appreciable percentage of these salts; (2) connate waters in underlying strata; (3) springs in or near the deposits; and (4) surface deposits of bentonitic glacial drift. Cole concluded that the probable source was the salts contained in the bentonites, which are widely distributed in the glacial drift. Surface waters carrying calcium salts in solution react by base exchange with the alkali silicates, releasing the salts contained in the bentonite in the form of soluble sulfates, and so forth. These in turn are concentrated and deposited in undrained lake basins.

More recent investigators have attributed the source of some sodium sulfate to the decomposition of rocks and sediments, such as bentonite, that also contain sulfates, and from the leaching of buried beds of sulfates. Organic-rich clay and shale also would produce sulfate through the oxidation of pyrite and marcasite (Davis and DeWiest 1966). A subaerial means of transport is provided because many playa lakes are hydrologically coupled with the surrounding water table. Sulfides are found in the organic-rich muds (containing stromatolites, etc.) and vegetative debris of some playa lake sediments. The fermentation of organics under anaerobic conditions would produce hydrogen sulfide, which could oxidize to sulfate (Reeves 1968).

McIlveen and Cheek (1994) reported that Grossman studied the sodium sulfate deposits of the Northern Great Plains of Canada and the United States in 1968 and attributed the origin of those deposits to the solution of deeply buried marine evaporites. In his model, groundwater from the Rocky Mountains moved downward and eastward into the Saskatchewan Subbasin during the Quaternary, leaching the buried evaporites of the Prairie Formation (Devonian). Ascending mineralized groundwater during the late Pleistocene discharged into stratified drift where freezing segregated pure crystals of sodium sulfate in micrometric (chemically stratified and stagnant) lakes.

In a later study, Last and Slezak (1986) questioned the dissolution of deeply buried Paleozoic evaporites as the ultimate source of the salts based on the incompatible brine chemistry. Their paper describes the origin of the basins, in addition to the hydrochemistry, mineralogy, sedimentology, and diagenesis of the deposits in western Canada.

The USGS studied the saline lakes in west Texas to investigate the hypothesis that the source of salts in the basins originated from connate waters or brines migrating from deeply buried Paleozoic evaporites or from Cretaceous rocks that crop out in the lake basins. They concluded that the origin of the deposits was, and is, by evaporative concentration of the runoff of potable groundwater discharging from the shallow High Plains Aquifer. Their study dealt with an analysis of hydraulic heads and pore volume flushing in addition to evaluation of solute ratios and isotopic chemistry (Wood and Jones 1990).

A subsequent article (Wood and Sanford 1990) dealt with the ratio of groundwater outflow to inflow (flux ratio) in hydrologically open basins and the resultant mineralogy and volume of precipitated salts. In addition, possible mechanisms by which brine could escape from the system are discussed. The authors developed a groundwater model, PHRQPITZ, to define the effects of various flux ratios on the mineralogy and thickness of deposits. Another paper (Sanford and Wood 1991) investigates two typical waters, seawater and Na-HCO₃ groundwater, to demonstrate the importance of basin leakage on brine evolution.

OCCURRENCE, RESERVES, AND PRODUCTION

Several countries have sodium sulfate deposits of sufficient size and purity for commercial mining (Figure 2). The principal producing countries are Spain, Mexico, Canada, the United States, China, Turkey, Iran, and Chile. Of lesser importance are Argentina, Egypt, South Africa, and the former U.S.S.R. (Garrett 2001). Although data on mine production for natural sodium sulfate are not available, total world production is estimated to be about 4 Mt, and total world production of by-product sodium sulfate is estimated to be between 1.5 and 2.0 Mt (Kostick 2004).

Spain

Spain appears to have some of the largest glauberite-thenardite deposits in the world. They contain an estimated 2.5 billion t of equivalent sodium sulfate, of which the recoverable reserves are about 272 Mt. The majority of these reserves are in the Madrid Basin or Tajo Basin in the central part of the country, about 50 km south of the country's capital, and the Ebro Basin in northeast Spain (Garrett 2001). Spain's four sodium sulfate producing companies are FMC Foret, S.A.; Sulquisa S.A.; Crimidea, S.A.; and Minera de Santa Marta S.A. (Recursos Minerales 2003).

In the Madrid Basin, the principal mines are the El Castillar and Sulquisa. The El Castillar deposit is located in Villarrubia de Santiago, Toledo Province, where beds of thenardite 5 to 8 m thick are mined by the underground room-and-pillar method. The ore horizon contains only a small amount of glauberite but rests on a thin glauberite layer with a clay marl and halite underneath. The horizon extends more than 30 km² and contains probable reserves of 200 Mt of Na₂SO₄. Composition of the ore is reported as 70% to 75% sodium sulfate, 11% to 17% calcium sulfate, 0.4% to 0.6% sodium chloride, 3% to 9% clay, and 1% to 5% moisture (McIlveen and Cheek 1994). FMC Foret operates the mine and a plant producing anhydrous sodium sulfate.

Near Villacónes, the Sulquisa deposit consists of thicker, higher-grade glauberite deposits. About 20 m of thoroughly leached overburden overlies a high-grade glauberite bed 25 to 45 m thick

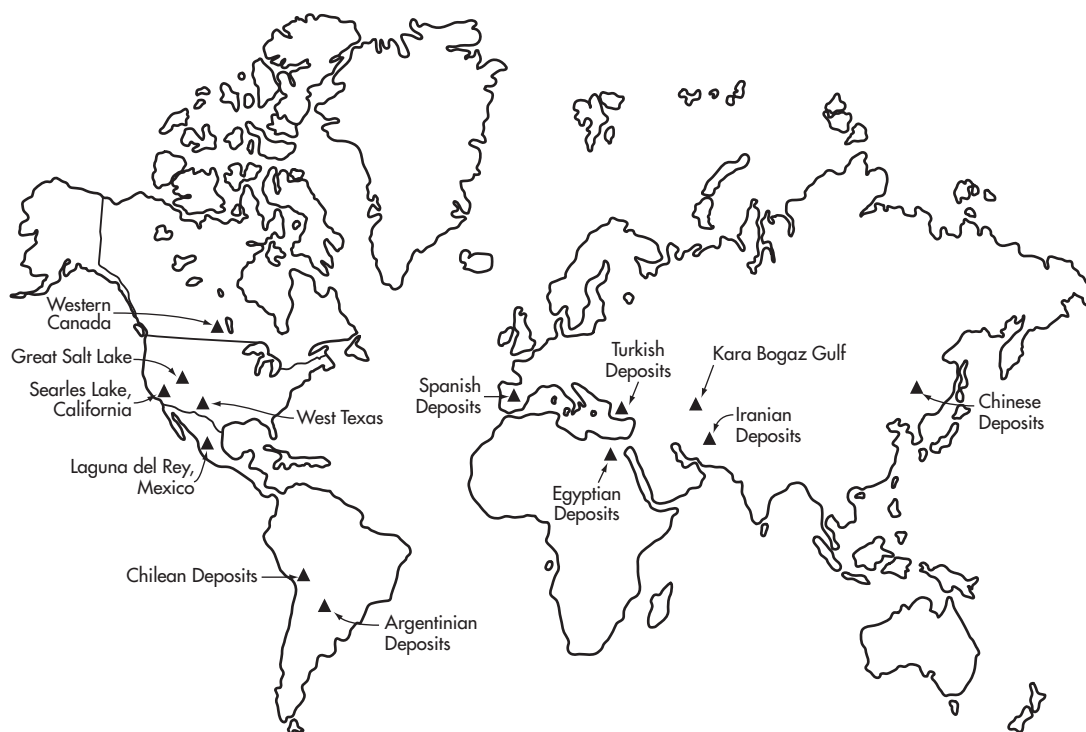

Figure 2. Principal sodium-sulfate-producing deposits of the world

containing some centimeter-thick interlayers of crystalline magnesite and magnesian shale. The ore is basically quite pure, averaging 40% to 42% Na_2SO_4 .

The Ebro Basin is an elongated and conformed depression of approximately 50,000 km^2 . The basin's lacustrine fill is Tertiary, and its important sediments range in age from Early Oligocene to Late Miocene. The sediments are up to 3 km thick, with zones that are predominately gypsum, interlayered with fine-grain siltstones and mudstones. There are three sub-basins containing glauberite: Rio Tiron-Belorado, Alcanadre-Arrubal, and Remolinos-Zaragoza (Salvany and Orti 1994). As the depocenter shifted from Zaragoza (the eastern and oldest) to Rio Tiron-Belorado (the western and youngest), the glauberite changed character from having considerable halite and some thenardite to being very pure with only a small amount of halite in the underlying clay. There is open-pit production at Cerezo del Rio Tiron by Crideros Minerales y Derivados, S.A. (Crimidesa), in Burgos Province and at Belorado by Minera de Santa Marta (MSM). These operations are rated at capacities of 500 and 240 ktpy, respectively.

The Calatayud Basin also contains very large deposits that are less well studied and are not known to be developed commercially.

Total production of natural sodium sulfate from Spain has increased. For 1999, it was estimated to be 600 kt, ranking it first in world production (Garrett 2001). In 2003, the estimated production was 907 kt, of which 728 kt was from glauberite and 179 kt was from thenardite (Recursos Minerales 2003).

Mexico

In 1999, Mexico produced 600 kt of natural sodium sulfate (Garrett 2001), making it the second largest producing country in the world. One of the world's largest sodium sulfate deposits, and the world's largest production of sodium sulfate in 1999, occurred at Laguna

del Rey in northern Coahuila, approximately 160 km north of Torreon (Garrett 2001). The evaporite lens consists of glauberite (averaging 50%; $\text{Na}_2\text{SO}_4 \cdot \text{CaSO}_4$) and bloedite (averaging 20%; $\text{Na}_2\text{SO}_4 \cdot \text{MgSO}_4 \cdot 4\text{H}_2\text{O}$), the latter as thin beds and irregular aggregates.

The crystal bed is 10 km long and 4 km wide, with 35 m thickness at the center. Its area is 40 km^2 , its volume is 560 million m^3 , and it contains approximately 350 Mt of sodium sulfate. The main concentration of bloedite, which occurs as short prismatic, monoclinic crystals or as extremely fine-grained masses, is found as a layer 1 to 2 m thick, located about 8 m below the top of the evaporite mass. Mirabilite and epsomite occur in minor proportions. The formation underlying the crystal bed is impervious clay and silt containing some sodium chloride. Glauberite occurs as thin tabular crystals and bloedite is found in massive concentrations. The intercrystalline spaces, amounting to as much as 25% of the evaporite mass, are partially filled with clay, and the rest with a brine in equilibrium with the solid phase.

A composite average analysis of brine from a depth of 20 m from several wells in the lake bed showed 18.46% sodium sulfate, 5.91% sodium chloride, and 5.28% magnesium sulfate. Analysis of several cores of the crystal bed showed 35% to 36% sodium sulfate and only 1.5% to 1.8% sodium chloride. Magnesium sulfate ranged from 4.7% to 12.7%. Estimated reserves are approximately 160 Mt of anhydrous sodium sulfate.

Sodium sulfate is produced at Laguna del Rey by Quimica del Rey, S.A. de C.V., a subsidiary of Industrias Penoles, S.A. de C.V. The plant was built in 1963 with a capacity of 30 ktpy. In 1988, the plant was expanded to its present capacity of 510 ktpy.

Other deposits are known to occur in northern Coahuila and in the state of Chihuahua, but in size and sodium sulfate content, they are smaller than the deposit at Laguna del Rey.

Sulfate de Viesca recovers 22 ktpy of sodium sulfate as a by-product from production of sodium chloride from natural brine. The plant is near Viesca in the southwestern part of Coahuila.

Deposits of thenardite occur in the state of Sonora near the municipality of Bacardahuachi, some 190 km northeast of Hermosillo. Outcroppings of thenardite and efflorescences in the soil occur discontinuously along the east side of the Bacardahuachi Valley in an area approximately 6 km long and 4 km wide. The deposits occur within the Baucrit Group (Oligocene). The outcroppings are covered by unconsolidated surface material, which varies in thickness between 10 and 30 m. Four workings have been developed within this area. In the largest pit, the Oro Blanco, the thenardite is reported to attain a thickness of 20 m. Analyses of selected samples from the Oro Blanco ran between 95% and 99% Na₂SO₄ (Anon. 1981).

During 1982, Para Mex, the Mexicanized affiliate of the Spanish company Tolsa, had conducted some exploration of the Oro Blanco and was evaluating the commercial possibilities of producing sodium sulfate from this area.

In 1999, Quimica del Rey, the country's main producer, had a plant capacity of 620 ktpy with about 250 wells at Laguna del Rey with only 70 to 80 needed to supply the plant (Garrett 2001).

Canada

Numerous saline lakes containing sodium sulfate are known on the western plains of Canada. Seventeen deposits contain more than 1 Mt each. Only one of the large deposits is in Alberta; the remainder are in Saskatchewan. Their commercial exploitation began in 1918 at Mukiki Lake, near Saskatoon, Saskatchewan (Last and Slezak 1986). At present, only Millar Western near Palo and Saskatchewan Minerals near Chaplin produce sodium sulfate.

An interesting occurrence of sodium sulfate has been reported at Castleguard Cave, which drains the Columbian Icefields of the Canadian Rocky Mountains. The mirabilite occurs in association with gypsum and epsomite (Younge and Krouse 1987). Though of geological interest, this occurrence is apparently noncommercial.

Commercial deposits of sodium sulfate are located in the Prairie Provinces of Canada where they occur in basins and depressions in glacial drift that lack apparent outlets. In general, the deposits are crystalline beds that underlie saturated brine lakes containing a few millimeters to approximately 1 m of brine in the spring and summer. The deposits contain two recognizable phases of crystalline beds—intermittent and permanent.

The intermittent beds form on the bottom and along the shores of the lakes. They crystallize and redissolve with fluctuations in temperature. This can occur in a matter of hours, but as winter sets in, less solution of the crystals occurs, causing the beds to become thicker and more compact.

The permanent beds underlying the lake usually are interstratified with thin layers of mud, clay, and organic matter. These beds range in thickness from less than 1 m to several meters. At Ingebrigt Lake, permanent beds are reported (Cole 1926) to cover 2.7 km with an average thickness of 6.7 m. In one part of the deposit, a thickness of 42.4 m was measured. Cole estimated the tonnage of hydrous salt in Ingebrigt Lake to be 22.7 Mt. A more recent evaluation is 8.2 Mt of anhydrous sodium sulfate (Broughton 1977).

Most of the deposits currently in production contain several million tons of sodium sulfate. The one deposit in Alberta contains 2.7 Mt (Watson 1980); estimates of total reserves in Saskatchewan range between 54.4 and 181 Mt. Another evaluation places the total anhydrous sodium sulfate reserve at 54.4 to 63.5 Mt and evaluated commercial reserves at 27.2 to 36.2 Mt (Broughton 1977). An

updated estimate of reserves would account for the tonnage mined since then.

Current capacity is reported at approximately 613 ktpy though production has never been close to reported capacity. The termination of Agassiz's production reduced this figure to an effective capacity of approximately 453 ktpy. This could presumably increase by 160 ktpy should a new owner reopen the Agassiz operations. About 253 ktpy of capacity belongs to Saskatchewan Minerals, which is owned by Dickenson Mines, Limited (Goldcorp, Inc.).

In 1999, Canada produced about 350 kt of natural sodium sulfate and a significant amount of by-product and synthetic sodium sulfate (Garrett 2001). At that time, natural sodium sulfate was produced by Saskatchewan Minerals from their Chaplin Lake and Ingebrigt Lake properties and by Millar Western from their Whiteshore Lake property. All three are in Saskatchewan. In 2002, the Ingebrigt Lake property was closed (CIM 2001). In 2005, the Saskatchewan government listed the annual production of sodium sulfate in the province at about 530 kt and from five plants, but apparently two plans produce only sodium sulfate—Saskatchewan Minerals and Millar Western (Saskatchewan Industry and Resources 2005).

United States

Deposits of sodium sulfate are found in Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, North Dakota, Oregon, Texas, Utah, Washington, and Wyoming. At the present time production is chiefly from brine deposits at Searles Lake, California, and in west Texas. Small quantities have been produced from saline lake deposits in Wyoming. Most of the southwestern brines are in dry lakes or playas underlain by beds of mirabilite, thenardite, and other evaporite salts. In the northwestern United States, the deposits associated with saline or intermittent dry lakes are similar in origin and composition to the Canadian deposits. Except for the brine deposits in west Texas, the deposits of the Southwest are chemically more complex than the northern deposits.

California

California has several sodium sulfate deposits. Dale Lake, Durmid Hills, Soda Lake, and Danby Lake have a record of past production but are not now producing (Smith 1966). Owens Lake has reserves of 10.9 Mt but has not produced any sodium sulfate (Kostick 1980).

At Searles Lake, minerals have been extracted from brines since 1873. Sodium sulfate was first produced in 1914. Searles Lake currently is the leading source of natural sodium sulfate in the United States (Moulton 1980). It probably has produced more sodium sulfate than any other deposit in the world. The Kerr-McGee Chemical Corporation operated the deposit for many years, but in November 1990 the operation at Trona, California, was purchased by the North America Chemical Company (Kostick 1990) and then by I MC Chemicals Inc., now known as Searles Valley Minerals Inc.

Sodium sulfate and other usable salts are produced at Searles Lake from brine underlying a large playa. The surface of the playa covers an estimated 155 km², but the central part, which forms the main deposit, is about 30 km² (Graubau 1920). A hole drilled by Kerr-McGee Corp. in 1968 encountered 930 m of basin fill and bottomed in quartz monzonite (Moulton 1980). Figure 3 shows the salt deposits in cross section.

Brine occurs in the interstices of the salt deposits. Ions present in the brine are sodium, potassium, carbonate, bicarbonate, sulfate, chloride, and borate. The upper salt, lower salt, and mixed layer are the productive zones, each contributing a distinctive brine to meet

Adapted from North American Chemicals Inc. company materials

Figure 3. Cross section of Searles Lake, California

the individual requirements the plants. In some instances, solar concentration of the produced brine is used to improve plant efficiency (Moulton 1980).

A plant expansion under way in 1977 was to bring capacity to 590 ktpy (Parkinson 1977). The plant never operated as planned and, in fact, in 1982 Kerr-McGee shut down about half of their sodium sulfate capacity, so output dropped to about 200 ktpy.

Utah

Sodium sulfate is no longer produced from natural brine at Great Salt Lake, Utah. Thick beds of mirabilite, intercalated with thin clay layers, have been found beneath the lake at several localities. Mirabilite crystallizes and sinks to the bottom of the lake during the winter. A layer of mirabilite 0.15 to 0.30 m thick occurs seasonally over large areas of the lake. Under favorable conditions, it is carried by winds and currents to the shore where it accumulates to a depth of 0.3 m or more. Strand deposits as thick as 3 m have been observed.

The Great Salt Lake is estimated to contain 3.8 Gt of salt, 342 Mt of which are sodium sulfate (Cohenour 1966). Great Salt Lake Minerals and Chemical Corp., an affiliate of North American Chemical Co., estimated that the playa contains 408 Mt of sodium sulfate (Kostick 1980).

On the north end of the lake, near Ogden, Great Salt Lake Minerals and Chemicals Corp. operates 69 km of evaporation ponds and a plant complex for producing potassium sulfate and magnesium chloride. Although sodium sulfate is no longer produced, common salt continues to be produced. The first production of sodium sulfate was reported in 1970. The operation had a sodium sulfate capacity between 22.7 and 32.9 ktpy.

Texas

The Ozark-Mahoning Company operated four sodium sulfate deposits in west Texas until 1987 when three of them—Rich,

Mound, and Brownfield lakes—were shut down and mothballed because of economic and climatologic conditions. The company had produced sodium sulfate from brine in west Texas continuously since 1933. The Texas deposits underlie playas and occur as brine and crystalline mirabilite. The brine contains mainly sodium chloride and sodium sulfate, with lesser amounts of magnesium and potassium salts, and is produced from wells 30.5 m deep. A fifth deposit, Soda Lake, near Monahans in Ward County, was abandoned in 1970 after nearly 40 years of continuous operations, during which time more than 1 Mt of anhydrous sodium sulfate were produced.

Cedar Lake deposit, near Seagraves, covers a surface area of about 21 km². It is the only deposit currently in production. Beds of crystalline salts are minimal, but strata containing saturated brines are found from near the surface to a depth of 30.5 m. The shallower strata contain brines of low salt content and are less productive. Richer brines come from beds 12 to 30.5 m below the surface. Brines from the Cedar Lake deposit contain about 10.5% sodium sulfate, 14% sodium chloride, and 1% each of magnesium and potassium.

The Brownfield Lake deposit, 16 km east of Brownfield, covers an area of about 4 km². The main deposit lies outside the boundary of the present dry lake surface. Saturated brine was produced from crystal beds at depths from 9 to 30.5 m. These beds, which contain thin layers of clay and silt, range from 1 m to as much as 4 m in thickness. The brine contains 15% sodium sulfate and 10% sodium chloride. A solution mining project to extract the crystalline reserve was developed.

The Rich Lake deposit, 19 km north of Brownfield Lake, produced sodium sulfate-bearing brine from a crystal bed averaging 2 m in thickness. The brine was transported by pipeline to the Brownfield Lake plant for processing. Ozark-Mahoning operated plants at Brownfield Lake and Cedar Lake. The combined capacity of the two plants was 159 ktpy.

A fourth deposit, Mound Lake, is located 13 km north of the Brownfield Lake plant. The lake has an area of 5 km², and lacustrine sediments occur to a depth of 24 m. The major portion of the reserve is brine similar in composition to that of Cedar Lake. A significant tonnage of mirabilite also exists. Mound Lake began producing in April 1981, and the brine also was transported to the Brownfield plant for processing.

The Brownfield plant, in addition to its sulfate deposits at Rich and Mound lakes, is being kept on a care-and-maintenance basis and could be reopened pending an improvement in the sodium sulfate market.

Arizona

At the Camp Verde deposit in Yavapai County, Western Chemical Co. mined solid beds of thenardite of varying thickness for many years. The deposit is unusual, because pure anhydrous sodium sulfate occurring in solid crystal form is rare. The deposit consists of layers of thenardite and other sodium salts interbedded with clay, which form a part of the Verde Formation. The total thickness of the beds is at least 46 m. Mining was done in a large quarry by underground room-and-pillar methods. The last mining was done by Arizona Chemical Co., a subsidiary of American Cyanamid Co., in 1934 (Ralston 1949).

Nevada

Nevada's principal producing deposit in years past was Rhodes Marsh, near Mina in Mineral County. The deposit covers 28 km². Production was confined mainly to the central portion of the deposit, where a bed of solid thenardite 1 to 2 m thick was mined (Ralston 1949).

New Mexico

A sodium sulfate deposit is known near Alamogordo in Doña Ana County. In Eddy County, near the potash mines, brine wells containing appreciable amounts of sodium sulfate and magnesium sulfate have been reported (Lang 1941). These wells were produced by Ozark-Mahoning from 1951 through 1957; the brines were trucked to Ozark's plant near Monahans, Texas, for processing. The wells depleted rapidly and were abandoned.

North Dakota

The sodium sulfate deposits of northwestern North Dakota are in Divide, Williams, Mountrail, and Ward counties. They are a southeasterly extension of the deposits in Saskatchewan. The Lewis and Clark Expedition first noted the sodium sulfate in North Dakota. Several lakes are known. The Federal Emergency Relief Administration (FERA) investigated and prospected most of them in 1934. The U.S. Bureau of Mines (USBM) in 1948 made an important reevaluation based on drilling (Binyon 1952).

The sodium sulfate content is generally high; sodium chloride, magnesium sulfate, and calcium sulfate are the main impurities. The USBM reported tonnages occurring in 18 lakes. They estimated that nine of the largest each contain more than 1 Mt of Glauber's salt. The major portion of the reserve occurs in the permanent and intermittent crystal beds, and only a minor portion occurs in the form of brine. Total reserves are reported to be 25 Mt of Glauber's salt or 11 Mt of anhydrous sodium sulfate (Binyon 1952; Crosby 1973).

The Grenora Lakes area contains three medium-sized sodium sulfate deposits—Grenora No. 1, Grenora No. 2, and Stink—with combined reserves of 6.9 Mt of Na_2SO_4 (Murphy 1996; Garrett 2001). Grenora No. 2, the largest deposit, covers 2 km². FERA drilling showed the maximum thickness of the permanent crystal bed to be 24 m and the average thickness to be 3.66 m. USBM estimated that the deposit contained 5 Mt of Glauber's salt or 2.2 Mt of anhydrous sodium sulfate (Binyon 1952). Drilling conducted by Ozark-Mahoning in 1977 generally corroborated the Bureau's estimate. Ozark-Mahoning owns Grenora No. 2 but it is not favorably located for economical exploitation.

Other States

A number of deposits in Montana, Washington, and Wyoming are not considered economically important because of their location and size, even though their composition is similar to the Canadian deposits.

China

Information on sodium sulfate in China, though available, is not readily attainable; therefore, not much is known about the geology of deposits. One known occurrence is a salt lake at Yuncheng, north of the Zhongtiao Mountains in Shanxi, which has been a source of salt for centuries. Chemical plants around the lake use brine containing significant amounts of boron, bromine, calcium, and iodine in addition to sodium sulfate and other sulfur compounds. Production from Yuncheng reportably accounts for 60% of China's output of mirabilite (Chin 1986).

An aquifer brine with high concentrations of sodium sulfate occurs 10 to 15 km west of Pengsham City, Szechuan Province, on the western bank of the Minkiang River. The brine occurs at a depth of 18 to 50 m primarily in a band about 20 km long and 1 to 6 km wide that is roughly parallel to the river, with a second small band 0.5 by 2 km just north of the city. The brine is pumped from hundreds of wells into solar evaporation ponds where mirabilite is crys-

tallized in winter and then dehydrated to form an anhydrous product. The brine occurs in Cretaceous and Middle Triassic limey clay that contains anhydrite crystals. It averages 97.8 g/L Na_2SO_4 , and reserves are reported to be 4.65 Mt of sodium sulfate (Hou and Yang 1938; Garrett 2001).

Mirabilite has been reported at the 200,000-km² Qaidam Basin, in Qinghai, which contains 20 major salt lakes. Mineralization in the basin includes mirabilite, boric acid, and lithium, in addition to sylvite and salt (Chin 1983; Garrett 2001).

Sodium sulfate also occurs with several of China's large soda ash deposits, such as at Chaganor. The Pleistocene deposit is located in the central part of the Inner Mongolia Autonomous region, 80 km south east of Erlianhot. The deposit covers 21 km², with nine porous brine-filled beds of salts containing about 11.3 Mt of sodium carbonate and 4.5 Mt of sodium sulfate (Garrett 2001).

In 1999, China produced an estimated 300 kt of natural sodium sulfate, 27 kt of sodium sulfate as a by-product, and 30 kt of synthetic sodium sulfate (Garrett 2001).

In 2003, a new anhydrous natural sodium sulfate operation with an annual capacity of 200 ktpy came onstream near Xishunhe in Hongze County, Jiangsu Province. The plant uses mirabilite from the only large sodium sulfate deposit in east China. A second facility in the area owned by a Chinese chemical company and a Spanish sodium sulfate producer has an annual capacity of 600 ktpy, making the region the world's largest natural sulfate production base (Kostick 2004).

Turkey

Natural sodium sulfate is produced in Turkey, although output is not large. First production recorded was in 1963, when 1.264 kt were produced. Output has increased steadily, and production in 1990 was about 80 kt, making it seventh in world production (Kostick 1991).

Several saline lakes in southwestern Turkey contain appreciable amounts of sodium sulfate. Tersakan Lake is about 160 km south of Ankara, near the town of Cihanbeyli. The lake, 13 km long and 4 km wide, covers 52 km². Its sodium sulfate content is greater than 8%. Sodium chloride and magnesium sulfate are present in amounts less than 5% and 2%, respectively, and because the calcium lake water has been impounded to induce evaporation, the sodium sulfate content of the brine increases. In the bottom of the ponds, crystalline layers more than 95% pure have formed.

At Aci Gol, a large lake 56 km east of Denizli, the saline content is similar to that of Tersakan Lake, although the sodium content is slightly lower and the content of sodium chloride slightly higher. Aci Gol is more than 26 km long, nearly 10 km wide, and has a surface area of about 200 km².

Production of sodium sulfate has come from Aci Gol: Alkim Alkali Kimya (in addition to two small lakes), Sodas Sodyum Sanayi, and Otuzbir Kimya Ltd. (Karayazici 1988). In 1999, Turkey produced 183 kt of natural sodium sulfate, 79 kt of by-product, and 71 kt of synthetic sodium sulfate for a total of 333 kt of product (Garrett 2001).

Iran

Iran produced 185 ktpy of sodium sulfate in the year ending March 1990; down somewhat from their peak production of 265 ktpy in the year ending March 1988. In 1990, production was from 13 mines in the provinces of Markazi, Semnan, and Teheran (L. Antonides, personal communication). Considerable sodium sulfate is produced as a by-product or coproduct of Urmiah (Reziieh) Lake's K_2SO_4 production. In 1999, Iran produced an estimated 180 kt of natural

sodium sulfate, 214 kt of sodium sulfate as a by-product, and 39 kt of synthetic sodium sulfate (Garrett 2001).

Chile

Small amounts of natural sodium sulfate are produced from playa deposits in northern Chile. The deposits are in the Atacama Desert, which lies along the west side of the Andes between the mountains and the Pacific Ocean, at an elevation of about 1,067 m. Some additional output is by-product from the nitrate industry. In 1999, Chile produced an estimated 150 kt of natural sodium sulfate, 16 kt of sodium sulfate as a by-product, and 20 kt of synthetic sodium sulfate (Garrett 2001).

Argentina

Many salt lakes and playas, some of which contain rich deposits of sodium sulfate, are located in Argentina, on the arid plateaus and in the intermontane valleys of the Andes (Wells 1923).

A large playa deposit of mirabilite and other salts is located in northwestern Argentina in Jujuy Province. The deposit is in the Andes at an elevation of 3,353 m. A permanent bed of mirabilite covering 53 km² occurs in the middle of a dry lake bed. The permanent bed, covered by a thin layer of sodium chloride, calcium sulfate, and sand, is reported to be 4.6 m thick at the center of the deposit and gradually thinner toward the edges. Subsurface waters from melting snow in the surrounding mountains feed into the lake and thus furnish a supply of brine year-round.

Production of natural sodium sulfate in Argentina decreased from 32 kt in 1986 to 15 kt in 1999. In that same year (1999), by-product sodium sulfate was 15 kt, and synthetic sodium sulfate was 43 kt (Garrett 2001).

Africa

A series of salt pans, some of which contain sodium sulfate, occur in the deserts and velds of the South African uplands. To date, none have been commercially exploited. In 1968, however, Associated Sulfate (Pty.) Ltd. was established to build a plant to produce sodium sulfate using raw materials from solar salt pans and effluent from the Rustenburg platinum plant.

Many alkali lakes and playas found in South Africa contain brines and a mixture of salts, such as Britten and Hagenstad pans. Some contain mirabilite-thenardite deposits and a high-sulfate brine, but as of 1999, there was only modest sodium sulfate production from these lakes. Most of the production potential is for sodium sulfate as a by-product from sodium chloride production (Garrett 2001).

About 110 Mt of sodium sulfate reserves exist in the Makgadikgadi Basin of Botswana (Massey 1973; Kostick 1980). For more than 40 years, various parties have considered developing, or attempted to develop, this large deposit, which covers more than 900 km².

In March 1991, a plant was completed at Sua Pan by Soda Ash Botswana (Pty.) Ltd., owned 52% by a South African consortium and 48% by the government of Botswana.

Production of 300 ktpy of soda ash and 650 ktpy of common salt was predicted to occur some 2 years after the initial startup of the plant. Garrett (2001) reported that as of 1999, no sodium sulfate production had occurred. Sodium sulfate and potassium chloride are mentioned as possible by-products (Antonides 1988).

Sodium sulfate deposits are found in the northern part of the Western Desert of Egypt, some 80 km west of the Nile Delta. Twelve principal lakes occur for 25 km along the axis of Wadi El Natrun, a minor tectonic depression. Some of the larger lakes remain permanently flooded, whereas the smaller lakes dry up seasonally.

Upon exploration, one of the latter, Beida Lake, was discovered to contain probable reserves of the B category, exceeding 1.1 Mt of thenardite and about 100 kt of halite. In 1999, Egypt produced an estimated 25 kt of natural sodium sulfate, 42 kt of sodium sulfate as a by-product, and 3 kt of synthetic sodium sulfate (Garrett 2001).

Commonwealth of Independent States

Production of sodium sulfate from bedrock and playa deposits has steadily been decreasing since the demise of the former U.S.S.R., from a high of more than 350 kt in 1989 to less than 50 kt in 1999. In the same period, production of sodium sulfate as a by-product and synthetic material both maintained production rates of more than 350,000 tpy (Garrett 2001).

Many deposits containing sodium sulfate occur in the CIS, in a large area from the Black Sea to western China and farther north into west-central and eastern Siberia. The economically important deposits are in the Aral and Caspian depressions and in the Kalunda Steppe in Kazakhstan. Although literature on sodium sulfate deposits in the Russian republics is reportedly fairly extensive, it is not readily available and requires translation. The reader is referred to a paper by Dort and Dort (1970) that contains a summary of several publications on Russian deposits.

The largest known occurrence of sodium sulfate in the world is in the Kara Bogaz Gulf (Kara Bogaz Gol), an embayment on the eastern side of the Caspian Sea. It is separated from the Caspian by a bar with a narrow strait through which water flows from the sea into the embayment. In 1927, the gulf covered 18,000 km² and the average brine was about 8 to 9 m. The first salts were crystallized about 500,000 years ago. Three separate layers are present: the upper layer is at a depth of 0 to 0.3 m and is up to 3 m thick; the middle layer is at a depth of 5 to 8 m; and the lower layer is at a depth of 14 to 18 m. Gypsiferous-carbonate muds separate the salt layers by 2 to 5 m. Beginning in 1934, a drying cycle and lowering of the Caspian Sea resulted in less water entering the gulf (Garrett 2001).

Kolosov, Pustyl'nikov, and Fedlin (1974) reported that the Kara Bogaz Gulf experienced a final phase of intense desiccation between 1939 and 1948. Seawater then moved across the bar from the Caspian Sea at a reduced rate of 9 to 10 km per year. For a time, the movement of seawater into the bay apparently reached equilibrium with evaporation. After 1957 or 1958, no decline in water level or constriction of the bay's area or appreciable change in brine composition was observed. Gypsum and glauberite were being precipitated out of the saturated brine throughout the bay. Bloedite (astrakanite) and halite were being deposited locally. Some carbonates were being deposited in the zone of mixing adjacent to the strait.

As a result of concern over the declining water levels in the Caspian Sea, a dam was constructed in 1980 across the strait that had once replenished the Kara Bogaz Gulf with Caspian seawater. This accelerated the severe desiccation of the gulf and, by 1983, no surface brine remained. Winds carrying sulfate dust traveled hundreds of kilometers, causing severe ecological problems (Levine 1988). Seawater was released to the gulf in 1984 at about 2 km³/yr (Kurilenko, Ruday, and Shvarts 1988). This, however, was apparently inadequate to solve the problem. Soviet scientists predicted that 80% of the minerals in the gulf would be irretrievably lost without adequate recharge from the Caspian Sea (Levine 1988).

The first commercial utilization of salts at Kara Bogaz Gulf, which began in 1929, used surface waters as a source of raw material. This source was abandoned, however, in 1953, because of the fluctuating hydrological and hydrochemical regimes of the gulf, and the operators began pumping the interstitial brines of the buried salt deposits as a feed source. Four recognizable salt horizons occur

to a depth of 18 m, each with distinct hydrological and mineralogical characteristics. Recent hydrological proposals by scientists from Leningrad State University and the All-Union Research Institute of Halurgy have recommended the following changes to the local brine industry: locating and developing production wells based on optimum hydrogeology and stratigraphy, lowering the brine output of each well from 500 to 250 m/hr, and using the end liquors from the plants to recharge the pay horizons (Kurilenko, Ruday, and Shvarts 1988).

In 1924, Kara Bogaz Gulf was estimated to contain 1 billion t of sodium sulfate (Grabau 1920). Later estimates of 2 billion t were reported (Goudge and Tomkins 1960; Hemy 1969). More recently, Russian sources indicate that reserves at Kara Bogaz Gulf may be lower than was previously thought (Kurilenko and Frolovskii 1982).

The Aral Sea is considered to be another rich source of sodium sulfate but the diversion of water from its two major tributaries, the Amu Darya and the Syr rivers, for agricultural purposes has resulted in a severe constriction of the Aral. Unless replenishment can be reestablished to counteract the evaporation loss, it has been predicted that the Aral Sea could be gone within another 30 years (Ellis and Turnley 1990). Although there have been later schemes to change this trend, *SurfWax Geography News* (2005) notes that the Aral Sea, once the world's fourth largest lake, is now the tenth largest, having shrunk by 39,994 km² since an atlas of the region was produced in 1967.

Some sulfate is produced in the central Asian republics that adjoin it. Lakes in western Siberia and in Kazakhstan are good sources but are not known to be currently producing except on a local scale. The steppe region around Kalunda, in Alta Kray, has a number of lakes rich in sodium sulfate. A sulfate combine was established on Lake Kuchuk, the largest of these (Hemy 1969).

Sodium sulfate and magnesium salts are produced from Kara Bogaz Gulf by Karabogazgolsulphate Combine. In 1990, the CIS ranked fourth in world production, producing an estimated 365 kt of natural sodium sulfate (Kostick 1990), mostly from the Kara Bogaz Gulf deposit. A 37.5-ktpy sodium sulfate unit was commissioned there in 1988 (Levine 1988). In 1999, Garrett (2001) estimated that the CIS produced 40 kt of natural sodium sulfate, 375 kt of by-product, and 365 kt of synthetic sodium sulfate for a total of 780 kt of sodium sulfate from all sources.

Antarctica

Because mirabilite is the first mineral, after ice, to appear in freezing seawater, it is not surprising that several occurrences have been noted in Antarctica. Mirabilite efflorescences commonly occur on the surfaces of rocks, glaciers, and sea ice; some occurrences are also reported farther inland.

Sodium sulfate has been described in coastal lakes that have been elevated and separated from the sea because of isostatic rebound. Other occurrences are reported in impoundments behind glaciers. The inland deposits are probably a result of seawater-derived salts transported with snow and accumulated in local depressions.

Though these occurrences are not economic, they are of geological interest. The reader will find them described in a paper by Dort and Dort (1970) along with a discussion of the low-temperature origin of sodium sulfate.

SYNTHETIC SODIUM SULFATE

Synthetic production was formerly grouped together under the by-product listings, which are still the predominant segment. It includes one of the faster growing segments of sodium sulfate production—that of reclaiming sodium sulfate from waste streams. For

many years, synthetic sodium sulfate has been a by-product or coproduct from the production of other chemicals. Now, because of its importance, synthetic sodium sulfate from reclamation processes has been added to this list of synthetic sodium sulfate sources. Important sources follow.

- *Manufacture of viscose rayon.* Sodium sulfate is generated in an acid spin bath by the neutralization of sodium hydroxide used to prepare the viscose solution. In the past, this source has been of almost equal importance with natural sodium sulfate on a worldwide basis. Growing popularity of other synthetic fibers coupled with environmental concerns, however, has resulted in reduced production. Of particular significance has been the replacement of rayon tire cord by other synthetic fibers, fiberglass, and steel. Nevertheless, rayon manufacturing continues to be an important source of supply. Avtex Fibers, Inc., a major manufacturer with nameplate capacity of 77 ktpy, ceased operation in November 1989 after encountering difficulty meeting environmental standards (Kostick 1990). Liberty Fibers Corp., Lowland, Tennessee, is the only rayon producer in the United States. They have a capacity to produce 38 tpy.
- *Manufacture of hydrochloric acid from sodium chloride and sulfuric acid in the Mannheim furnace and similar processes.* In the Hargreaves process, sulfur, steam, and air are substituted for sulfuric acid. Many years ago, the Mannheim furnace was the main source of sodium sulfate, and this chemical was truly a coproduct rather than a by-product. Because the salt discharge from the furnace tended to form cakes, it was named salt cake. This name remains as a trade designation for low-grade sodium sulfate. Large amounts of hydrochloric acid are produced today as a by-product in the manufacture of chlorinated hydrocarbons. As a result, the Mannheim furnace process is generally considered to be obsolete; in certain geographical areas, however, and in particular raw material situations, it continues to be an economically significant source of sodium sulfate.
- *As a by-product in numerous other processes* wherein certain sodium salts are converted to acids by reaction with sulfuric acid, or sodium alkalis are neutralized with sulfuric acid as part of the process. Current operating (or under construction) examples are the processing of chromium ores to produce sodium dichromate and the production of lithium salts, vanadium pentoxide, boric acid, ascorbic acid, phenol, formic acid, silicic pigments, and various catalysts. One aspect of several of these producers, both in this category and the preceding, needs to be noted: their ability to change the by-product. In the Mannheim furnace, for instance, if potassium chloride is substituted for the sodium chloride, then the by-product is potassium sulfate instead of sodium sulfate. It is an economic decision and might have to include some changes in some of the processing equipment. But, it is not just limited to this one process, and should the market become extremely depressed, or perhaps if alternative opportunities arise, there could be further switching by the by-product and coproduct manufacturers.
- *Reclamation.* This newly added category includes reclamation of sulfate values with final form of sodium sulfate from liquid waste streams and from flue-gas desulfurization (FGD) units, and reclamation of lead from discarded batteries. In the former, there have been a number of articles about the Aqua-Tech process by Allied-Signal, Inc., which treats sulfate-bearing streams from pulp mills, thus generating sodium sulfate for internal process use or sale to other pulp mills and with excess available for sale to the open market.

NOTE: For 1991, glass was combined with "other." For 1996, pulp and paper was combined with "other."

Figure 4. Sodium sulfate consumption in the United States since 1991

In 1985, USBM published its pilot work with the citric process for the FGD that has been installed in several coal-fired electric power generating plants. Engineering firms have made a number of inquiries about the processing from the Glauber's salt phase, the final product shown in the report, to a final anhydrous material for sale on the open market. If left with Glauber's salt as a final form, most areas at present would permit it to go to a landfill. An annual report by USBM shows two small producers with FGD as sources, which perhaps incorporate the citric or a similar process. It may be that this process is more attractive than FGD units which generate gypsum.

Natural sodium sulfate remains the source for about half the market in the United States and has remained important worldwide during the past decades. Although vast resources are available, producers of the natural material currently are aware of the threat from by-product sources. The outlook for the natural sodium sulfate business is certainly not the most promising it has ever been.

END USES

Detergents

In the United States, the detergent industry has displaced the pulp and paper industry as the leading market for anhydrous sodium sulfate (Figure 4). As used by the detergent industry, sodium sulfate is an inexpensive filler and diluent, because it is white, noncorrosive, and neutral. In addition, it is claimed to have very mild detergent properties. Formerly, about one third of dry home laundry detergent was sodium sulfate. Now it is much less than that, perhaps one sixteenth or even as low as one sixty-fourth. Dry laundry detergents are now losing ground to liquid home laundry detergents. The liquids now make up as much as 50 % or more of the home laundry detergent market.

Kraft Paper

At the beginning of the 1980s, the manufacture of kraft paper pulp was the principal use of sodium sulfate. It has now dropped to a distant second place, being almost the sole segment of decline for the consumption of sodium sulfate. In the early part of the decade, the substitution of emulsified sulfur and caustic soda, which was much cheaper than salt cake, first made an impact on salt cake usage. Synthetic suppliers who had formerly produced truly a salt cake—notably the rayon industry and similar by-product producers—had to upgrade their facilities to produce higher-purity material. This decline trend began in 1982 and continues because of more efficient kraft recovery systems and environmental rules and regulations. The potential for this industry to be a net producer of sodium sul-

fate was mentioned in the Synthetic Sodium Sulfate section of this chapter.

Glass

Another important consumer of sodium sulfate is the glass industry. Sodium sulfate has two favorable effects in the glass melter: it promotes early reaction with unmelted batch and it has an influence in the early stages of glass formation. Harben (1991) noted that a batch of container glass has about twice as much sodium sulfate as flat glass, at about 1% and 0.5%, respectively. This tracks to the concept that because sodium sulfate is an aid to the pliability of the glass, the more complicated the shape of the glass mold, the more sodium sulfate is used. It does appear that flat glass is much more demanding in certain aspects such as particle size and limits of certain chemical contaminants. Both commodities demand the least variation possible for all their raw materials, and sodium sulfate is definitely included.

Other Uses

The textile dyeing industry was once a large consumer of sodium sulfate in the United States; this industry, however, is mostly gone because offshore labor is less expensive for the textile industry. Without U.S.-produced textiles, there is little need for a domestic textile dyeing industry. The world's leading manufacturer of dyeing equipment, Gaston County Dyeing Machine Company, reports that using sodium sulfate reduces corrosion of the stainless-steel equipment used in the industry. A big impetus for the switch over from common salt to salt cake has come from the recent formulation of dyes that allow sodium sulfate to be as efficient as common salt in penetrating the dye to the center of the thread.

A number of other uses for sodium sulfate still are important, though the consumption is spread out to many small users rather than the few large users of the previous industries. It is used, for example, as an ingredient of stock foods and remedies, in the manufacture of inks, in tanning of leather, and in the manufacture of synthetic sponges.

The literature abounds with articles and patents for the use of Glauber's salt as one of the main ingredients in passive solar energy devices. The advantage it offers is that, with appropriate other salts, its phase change is at room temperature. It absorbs significant amounts of energy in the process of crystallizing and then as it melts it gives off energy at the same temperature. Thus, with the appropriate phase-change temperature and the appropriate salts in the mixture, it can moderate the heat load in warming an environment or, conversely, moderate the cooling load in keeping an enclosure cool. No commercial applications have made a lasting effect though. The problems (no single source is cited) stem from the mixture surviving only a finite number of phase changes and then having to be either recharged or replaced. New and better mixtures are claimed, but they have not as yet made their way to the marketplace with any success.

It is difficult to estimate worldwide consumption patterns because of great variations from one country to the next. Canada, Sweden, and Finland are large producers of kraft paper pulp, and perhaps 95% of the sodium sulfate consumed in those countries is used for this purpose. Environmental concerns are having effects overseas similar to those being experienced in the United States. In the United Kingdom, France, Germany, Japan, and many other countries, paper production is small, so the major consumption of sodium sulfate is in detergents, glassmaking, production of other chemicals, dyeing processes, and miscellaneous uses. Worldwide consumption patterns probably are not far from the estimate shown for the United States (Figure 4).

PRODUCT SPECIFICATIONS

Because there are no industry standards for designation of grades, types, or specifications, there is a proliferation of designations, most of which are not fully applicable throughout the industry they are supposed to describe. Detergent grade, for instance, has in common only purity—and even that is not completely uniform. A product that is 99.7% pure, yet has a trace of coloring, would not be acceptable to most detergent manufacturers. Those manufacturers in the detergent industry are further differentiated by their tolerance for varying amounts of common salt, iron, and also have individual particle-size considerations, sometimes completely at different ends of the spectrum from each other.

When perusing the literature, or perhaps when discussing the uses of sodium sulfate with those familiar with the industry and members of the fraternity of producers, it is not rare to hear or see the term *salt cake* applied loosely to mean all production of sodium sulfate. This term technically applies to sodium sulfate that is discolored, is lumpy, or has contaminants; these attributes preclude its use except by the pulp and paper industry or other industries that can tolerate such attributes and where it is sold at reduced prices. Salt cake in this latter, and more accurately narrow, connotation can range in purity from 90% to 99% Na_2SO_4 . As mentioned in the earlier discussion of the Mannheim process, the sodium sulfate produced was relatively impure and discolored, and it came out in the form of cakes—thus the term *salt cake*. It is synonymous with low-purity sodium sulfate. Only a few natural resource producers have selected this grade for production, most of the time as captive sources for the pulp paper industry. They are able to accomplish this production with very little refining required in the beneficiation process.

High purity, also referred to as technical grade, refers to anhydrous sodium sulfate with a purity of 99% or greater. Different consumers for the same end use may have quite different specifications. Particle size and strict limits on trace contaminants are important to almost all consumers of this grade of material. The glass industry, in particular, can be very strict about iron, copper, or any of the noble metals, with limits in the parts per million. Most production from the natural resource producers can meet these stringent limitations, but only with some earnest effort.

Glauber's salt (mirabilite), the decahydrate of sodium sulfate, was once an item of commerce. Because Glauber's salt has a melting point only slightly above room temperature and it effloresces when exposed to ambient conditions, anhydrous is preferred for most volume usage. Small quantities of Glauber's salt are still sold, however, for some special uses.

PROCESSING

No two operations are exactly alike for any of the natural producers. It is only after the point where Glauber's salt is delivered to the evaporative process that strong similarities are apparent. Even within the same company, or different companies operating in the same vicinity, the stages up to and sometimes through the crystallization of Glauber's salt are different. It ranges from minor, though notable, differences to extreme differences. After the Glauber's salt is fed to the evaporative system, however, the systems could be interchangeable for the same final product being desired. That is, paper-grade systems could be interchanged with each other or technical-grade (high-purity) systems might be interchanged and have little or no effect on the end product. It is the mining and extraction procedures up to this point that differentiate the producers. This is true worldwide. Each deposit differs somewhat in composition. Some of the deposits, such as those in Saskatchewan and Texas, are simple salts with only one product extracted. Those of

the Great Salt Lake and Searles Lake host a complex set of minerals, and a number of them are extracted in sophisticated processes in various forms and varieties. Yet, once the Glauber's salt is extracted, not too much difference remains in the final steps.

Canada

A number of structural changes have been made in the Canadian industry since the sixth edition of this book. Saskatchewan Minerals, formerly a Province Corporation, is now owned by Dickenson Mines, Limited (Goldcorp, Inc.). The Francana Operations at Metiskow, Capri, and Alsaska have all closed. At present, only two of the natural producers' locations are in production. These are Saskatchewan Minerals' plant at Chaplin, Saskatchewan, and Millar Western Industries Ltd., formerly Midwest Chemicals, at Palo, Saskatchewan. Both Canadian producers use seasonal temperature differences to assist in processing the sodium sulfate deposits. Brine accumulates on the lake bed and becomes nearly saturated in the late summer months. Then it is pumped to large reservoirs that may be more than 3 m deep. As cold weather sets in, Glauber's salt crystallizes from the saturated brine. The residual mother liquor, containing most of the magnesium and sodium impurities, is drained off. After draining, the Glauber's salt remains in the reservoirs until the coldest part of the season, usually January or February, when it is harvested and accumulated in stockpiles at the plant site.

A dredging system, pioneered by Orminston, was used in the 1990s at two of the lakes to supplement the stockpiled supply during the warmer season. Besides Orminston, Saskatchewan Minerals at Chaplin used a dredge in the warm weather. No Canadian company is using this process, however, in 2005.

Obviously, the Canadian plants are somewhat dependent on nature to produce the crystals of Glauber's salt. Drought or other unusual conditions can affect the production cycle. The plants try to keep more than 1 year's supply of Glauber's salt in their stockpiles to keep production from being interrupted by such conditions. This method has proved very successful in Canada, producing a salt cake of high quality.

To prepare a salable anhydrous product, the Glauber's salt must be dehydrated. Because of the inverse solubility of sodium sulfate (i.e., less soluble at higher temperatures), this is not a simple, straightforward operation. In the early days, dehydration was done in large rotary kilns, some of which were fired by lignite. None of the operating producers are using this method.

When Glauber's salt is melted, the solubility of anhydrous sodium sulfate in the water of crystallization is exceeded, causing precipitation. The balance of the water must be evaporated to produce an anhydrous product. Ozark-Mahoning's submerged combustion evaporators are used for this purpose by Millar Western Industries. The Saskatchewan Minerals plant at Chaplin uses a multiple-effect vacuum evaporator.

The choice of evaporative system is an economic issue, hinging mainly on two issues: initial capital cost and energy efficiency. The choice is either low capital cost, such as for submerged combustion evaporators and other direct-fired units with high operating cost for energy and maintenance, or high-energy-efficiency evaporators, such as the multiple-effect or mechanical vapor recompression evaporators, which have higher initial capital cost but enjoy low energy and operating costs. If high energy efficiency is chosen, a second issue is choosing between multiple-effect and mechanical vapor recompression evaporators. Then the selection criterion is the relative cost of electricity and gas or other heating fuel. The multiple-effect evaporators use more heating fuel and less electrical energy than the vapor recompression evaporators but can be more

cost-effective depending on the relative cost. It was the relative cost of fuel that prompted Saskatchewan Mineral's Chaplin plant to choose the multiple-effect over the vapor recompression evaporators when they replaced their Holland evaporator in 1983.

At all plants, the anhydrous salts precipitated in the evaporators can be separated from the saturated solution by mechanical means, including centrifuges and hydrocyclones, and the wet salt is finally dried in direct-fired rotary kilns. Parallel-flow dryers are now preferred for ease of control and fuel economy, whereas in the older processes countercurrent flow was used in the dryers.

Mexico

The brine processed at Quimica del Rey, S.A. de C.V., is very strong and probably saturated. It contains more than 26% sodium sulfate and appreciable amounts of chlorides and magnesium. About 65 wells produce the brine from a depth of approximately 12 m. The brine temperature is 25°C before precooling with the spent brine. The cooled brine is fed to a vacuum crystallizer where it is cooled to 9°C by evaporative cooling, causing Glauber's salt to crystallize. The slurry is thickened, filtered, and melted. Evaporation is accomplished in multiple-effect evaporators. Final drying is in co-current-fired rotary kilns. Part of the mother liquor is processed further for recovery of magnesia products and the balance goes to waste.

United States

The United States has also seen changes in corporate ownership. Kerr-McGee sold its Searles Lake plant to North American Chemicals Inc. in 1990. This is now owned by Searles Valley Minerals, Inc. (IMC Chemicals Inc. is an affiliate of Great Salt Lake Minerals and Chemicals Corp.). The largest production of natural sodium sulfate in the United States still comes from Searles Lake, California, even though output is much less than in the past. Before 1982, the Kerr-McGee Chemical Corp. plants made about 500 kt of sodium sulfate annually. The Trona plant, representing about half of the total sodium sulfate capacity, was shut down in 1982. Similarly, the Argus plant, which is the newest addition in the area, is not currently operating. The Westend plant now is Searles Valley's only source of sodium sulfate.

The Searles Lake brine is complex, and a number of salable products are extracted. At the Westend plant, sodium sulfate is recovered along with soda ash and borax. Mixed brines are first carbonated with carbon dioxide to precipitate sodium bicarbonate, which is removed by filtration. The decarbonated brine is cooled to crystallize borax. This borax is separated from the brine, which is then cooled further to produce a crop of Glauber's salt. After it is removed, a final cooling recovers a second crop of borax. Heating converts the sodium bicarbonate to soda ash and the borax is either crystallized as a hydrate or dehydrated to anhydrous form. The Glauber's salt is washed, melted, and recrystallized as anhydrous sodium sulfate. The following description of the Trona plant is included because it is of interest, even though the sodium sulfate part is shut down.

The Trona main plant cycle had three major process plants. The brine from the lake was cooled to produce a crop of Glauber's salt that was removed and dried to sodium sulfate. The resultant mother liquor from this step was processed further to recover potash and borax. A different brine was treated in a liquid-liquid solvent extraction plant to recover boron values as boric acid. After it was removed, mixed sodium and potassium sulfates were precipitated by evaporation, and these mixed sulfates were fed to the potassium sulfate plants. The Trona carbonation plant was somewhat similar to the Westend plant in that carbon dioxide precipi-

tated sodium bicarbonate, which was filtered and removed. Cooling then precipitated borax. Finally, burkeite, a double salt of sodium sulfate and sodium carbonate, was recovered and fed to the Argus process.

In the Argus plant, brines from the lake were mixed with burkeite solutions and streams from other plants to recover additional soda ash. Nothing has been published since Moulton (1980), so the details of plant practice at Trona are not available.

Cooper Natural Resources is the nation's second largest natural producer of sodium sulfate. Cooper Natural Resources operates the Dry Gulch plant (also known as the Seagraves plant) in Terry County, Texas, which has a capacity of 141 kt and has the Brownfield plant with a capacity of 64 kt on standby. Both plants use a refrigeration process to crystallize the Glauber's salts that had been developed in the early 1930s for a plant near Monahans, Texas. The Monahans plant closed in 1970 because the deposits were essentially exhausted. The Ozark submerged combustion burner used in the evaporative section of the old Monahans plant probably represented the first commercial application of submerged combustion in the United States.

The Texas brine contains both sodium chloride and sodium sulfate, as well as smaller amounts of magnesium and potassium salts. At the Brownfield plant, a portion of the brine was pumped through the Permian salt bed to introduce sodium chloride. The high sodium chloride content depressed the solubility of sodium sulfate, improving its extraction. At the Seagraves plant, sufficient sodium chloride is present in the brine; additional salt is not needed. The Texas climate does not lend itself to the production of Glauber's salt by atmospheric chilling, so mechanical refrigeration and heat exchange are required. The Glauber's salt formed in this manner is filtered and washed, yielding a product of high purity.

Melting and dehydration of Glauber's salt is accomplished by a mechanical vapor recompression evaporation system, which has much improved fuel efficiency over the former submerged combustion units, even after the Seagraves plant had been updated with a heat recovery system in conjunction with the submerged combustion units. Hydrocyclones and centrifuges separate the anhydrous crystals from the saturated solution, which is returned to the evaporators. The crystals are dried in parallel-flow rotary kilns.

Other Countries

Other than for Spain, little is published about processing in other countries. The little that has been seen is consistent with the earlier statement that the mining portion differs, extracting by incorporating some form for crystallization of Glauber's salt, and the evaporative portion is in line with the techniques applicable for the particular end use of the material. It can be reasonably assumed that methods used are similar to those used in the United States, Mexico, and Canada, wherein chilling by natural or mechanical means precipitates Glauber's salt, allowing separation from other salt. The Glauber's salt would then be dried to anhydrous sodium sulfate.

In Argentina, saturated brine from a lake bed is pumped to crystallization tanks where great night and day temperature variations result in precipitation of Glauber's salt. This is possible because the plant site is at an elevation of 3,353 m. The Glauber's salt is melted by heating; the precipitated anhydrous sodium sulfate is then separated and dried. There is no evaporation of water, so the saturated solutions probably are recycled through the system.

Deposits in Spain, one of the few countries where thenardite is the starting material, are mined underground and present special problems because the minerals contain an appreciable amount of calcium sulfate in the form of glauberite ($\text{Na}_2\text{SO}_4 \cdot \text{CaSO}_4$). Countercurrent leaching at temperatures between 35° and 40°C dissolves

most of the sodium sulfate, leaving calcium sulfate undissolved. The solids, which probably contain other insoluble impurities, are settled in large Dorr thickeners. A second leaching step with water at 29°C results in maximum recovery of sodium sulfate. Evaporation is carried out in a single-effect vacuum evaporator with forced circulation. Final drying is done in a fluid bed dryer with hot air heated by steam (McIlveen and Cheek 1994).

PRICES

Published price information for sodium sulfate usually only approximates the true market price. In the United States, prices usually are based on quotations from by-product sources located near consuming points. Because producers of the natural salt are located at great distances from most customers, the free on board (f.o.b.) plant value for natural material may be much less than the published price. On the other hand, in periods of shortages and rising prices, published information often lags behind actual selling levels.

In 1998, the terms “Most-Favored Nation” and “Non-Most Favored Nation” were discarded and “Normal Trade Relations” and “Non-Normal Trade Relations” came into use. By 1999, “Non-Normal Trade Relations” was no longer applicable and was not used. A few rogue nations without normal trade relations with the United States, however, face significantly higher tariffs. In 2003, the sodium sulfate (100% Na₂SO₄, bulk, f.o.b. works, in the East) was \$114 per 0.9 t. In regard to tariffs, crude (salt cake) was free, but anhydrous sodium sulfate had a 0.4% ad valorem tariff.

For tax purposes, a depletion allowance of 14% for both domestic and foreign deposits is permitted by the Internal Revenue Service.

ACKNOWLEDGMENTS

This chapter is revised from the 6th edition written by Sid McIlveen Jr. and Robert L. Cheek Jr. Much of the text is unchanged from the previous edition; however, statistics and other time-sensitive content has been modified to reflect current trends and knowledge.

The authors acknowledge the valuable assistance and suggestions received from Dennis Kostick, sodium compounds commodity specialist with the former USBM, and his equivalent with Energy, Mines, and Resources Canada, Patrick Morel-a-l'Huisier. Thanks also to S.W. Fletcher of the North American Chemical Company for review and permission to print the graphics on Searles Lake. The authors appreciate the review of the sections on Mexico and Spain by Alberto Ross of Servicios Industriales Penoles, S.A. de C.V., as well as the assistance of Tariq Mahmood; Alien Karpman of Elf Atochem; and Ruby Felan of Ozark-Mahoning for their chemical review, Russian translations, and manuscript preparation, respectively. Appreciation is extended to Warren Wood of the USGS for his help. The authors also thank the following specialists with the former USBM: Lloyd Antonides (Iran and Botswana), Hendrik Van Oss (Turkey), and Richard M. Levine (Russian republics). Dennis Kostick, now with the USGS, reviewed the revised manuscript.

Decorative Stone

George S. Austin, James M. Barker, and Scott C. Lardner

INTRODUCTION

Stone, one of the oldest building materials, today remains a well-established material used throughout the construction industry. It is still widely considered to be the most aesthetically pleasing, prestigious, and durable building material. The use of natural stone is much less prevalent now than in the past, though demand is rising. New and reopened quarries are coming online to meet increased demand related to new building technology and increased residential use of stone. Natural stone is becoming a key design element in modern homes. Buyers prefer low-maintenance natural materials inside and outside the home.

CLASSIFICATION

No classification can completely eliminate overlap between dimension stone, aggregate, and decorative stone because most stone is multipurpose. Much stone used for decorative purposes is not produced specifically for that end use. About 50% of the rock quarried for dimension stone becomes waste, which can be sold as decorative stone coproducts (Figure 1) composed of the exact stone used in the dimension stone side of the business. Thus, dimension stone and decorative stone are intimately intertwined. Many uses require a compromise between decorative and structural qualities (O. Bowles, personal communication).

Shipley (1945) used the term *decorative stone* interchangeably with *ornamental stone*. Gary, McAfee, and Wolf (1972) defined decorative stone as that used for architectural decoration, such as mantels, columns, and storefronts, but added that it is sometimes set with silver or gold in jewelry as curio stones. Bates and Jackson (1987) and Jackson (1997) also restricted decorative stone to that used for architectural decoration. Murhovich and others (2002) proposed doing away with the term “decorative stone” in favor of *decorative rock materials*. Meanings of otherwise identical terms used in the stone industry differ between geologists, engineers, and quarries; they often carry a much broader meaning for quarriers and engineers compared to their very specific use by geologists (Makens, Dobrell, and Kennedy 1972).

Geologist define decorative stone, including ornamental stone, more broadly as any stone used primarily for its color, texture, and general appearance. It is not used primarily for its strength or durability, as is construction stone, or in specific sizes, as is dimension stone. The decorative stone industry uses a much wider range of stone types, such as naturally rounded pebbles, compared

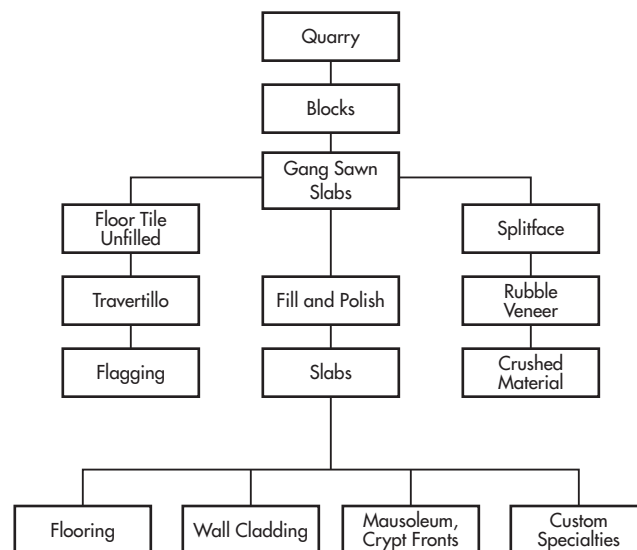

Figure 1. Materials flow from quarry (top) to numerous products, produced by New Mexico Travertine west of Belen, New Mexico. Travertillo is travertine tile with rounded corners similar to ceramic saltillos produced in Mexico.

to the dimension stone industry. Decorative stone usually serves some structural purpose, but it is not load-bearing to any great extent. Weak or costly stones that are attractive serve in solely decorative applications.

The basic types of decorative stone are rough stone, aggregate, cut or dressed stone, and synthetic stone:

- Rough stone (unprocessed or slightly processed)
 - Fieldstone (moss rock)
 - Flagstone
- Aggregate (lightly processed; screened or not)
 - Uncrushed stone
 - River rock
 - Scoria and cinder
 - Fused argillaceous rock

- Crushed stone
 - Rubble
 - Exposed aggregate
 - Dash
 - Terrazzo
- Cut or dressed stone (moderately to highly processed; no set size)
 - Statuary and objet d'art
 - Fireplace rocks and hearthstones
 - Ashlar
 - Monuments and memorials
 - Tile and paving blocks
 - Veneer and wall cladding
 - Miscellaneous
- Synthetic stone (made from various raw materials)

STATISTICS AND END USES

Decorative and dimension stone data are difficult to separate because the U.S. Geological Survey keeps statistics only on dimension stone, sand and gravel, and crushed stone. The value of domestic dimension-stone production in 2004, which includes some decorative stone, was about \$257 million compared to imports of about \$1.49 billion and exports of about \$64 million. Production in 2004 was 1.30 Mt, of which about 35% was for decorative uses (Dolley 2005). The principal uses are rough blocks in building construction (41%) and monument stone applications (25%). In 2004, dimension stones used or sold were granite (35%), limestone (28%), sandstone (13%), marble (5%), slate (1%), and miscellaneous stone (18%), by tonnage. Dressed stone was mainly sold for flagging (25%), ashlar or partly squared pieces (24%), and curbing (22%), with the rest miscellaneous or unspecified (29%), by tonnage (Dolley 2005).

Crushed stone was valued at \$9.7 billion in the United States in 2004. Imports were 15 Mt and exports were 2 Mt. About 1.61 billion t of crushed stone was consumed. Of the 806 Mt identified by use, 82% was construction aggregate, 15% for cement and lime and chemical or metallurgical manufacturing, 2% for agriculture, and 1% for miscellaneous uses. Crushed stone used for decorative purposes is scattered throughout several of these categories. Limestone and dolomite constitute about 86% and granite 8% of crushed stone in the United States. About 6% is sandstone and quartzite, miscellaneous, marble, calcareous marble, slate, volcanic cinder, scoria, and shell (Tepordei 2005).

Rough Stone

Rough stone is used as it is found in nature with very limited processing such as minor hand shaping, edge fitting, and size or quality sorting. This stone type is often marketed locally in relatively small tonnages and includes fieldstone and flagstone. The primary end uses of rough stone are landscaping, edging, paving, and large individual stone landscape or interior accents (Figure 2).

Fieldstone

Fieldstone is picked up or pried out of the ground (gleaned) without extensive quarrying and includes garden or large landscaping boulders (Hansen 1969; Austin, Barker, and Smith 1990). Boulders and cobbles can be split or roughly trimmed for use in rubble walls and veneers, both interior and exterior. Popular fieldstone rock types include sandstone, basalt, limestone, gneiss, schist, quartzite, and granite, but many others are suitable. Individuals or small companies

Figure 2. Medium-to-large stone, for use as accents, on display in a New Mexico stone yard

Figure 3. Slabby sandstone moss rock used in a retaining wall. The blocks are mottled by attached lichens.

collect much of the fieldstone because the industry is labor intensive and markets are small. Shipping costs often preclude selling fieldstone far from where it is collected. The stone can be sold in small quantities from the backs of vehicles (Austin, Barker, and Smith 1990). Fieldstone includes many rock types, sizes, and shapes, with the only common denominator that it must be set by hand and be durable (W.R. Power, personal communication).

Moss rock is fieldstone partially covered by algae, mosses, lichens, and fungi, which give the rock an aged and variegated patina (Austin, Barker, and Smith 1990). The plants are supported by moisture and nutrients in the stone. Moss rock is used for landscaping, walls, and fireplaces. Although almost any durable rock can be moss rock, most are slabby or rounded sandstone and limestone (Figure 3).

Flagstone

Flagstone or flagging consists of thin, irregular slabs used for paving, walkways, and wall veneers. Random-shaped flagging is produced widely in the United States. Suitable stone breaks very easily in one direction, producing flags. Any fissile stone can be

Figure 4. Ashlar blocks of Coconino Sandstone (Jurassic) used as a veneer for a wall of St. John's Cathedral, Albuquerque, New Mexico

Figure 5. Granite blocks used for curbing in a parking lot near Bar Harbor, Maine

used, but sandstone (bedding planes) and slate (cleavage surfaces) are best and dominate the market. Limestone and dolostone are quarried as flagstone in the Great Lakes area of the United States (A.M. Johnson, personal communication). The Coconino sandstone is quarried extensively in Arizona and produces very high quality, red-to-pink-to-white flagstone (Townsend 1962). Sandstone flags up to 0.5 m² can be split to a thickness of 3 cm or less. Flagstone slabs 3 to 10 cm thick are used for walkways in high-traffic areas; they must be resistant to abrasion and have low relief on the wear surface to minimize tripping. If used in walkways, these thin slabs must be set on a very firm base. Thicker flags of sandstone or granite can be used in walls (Figure 4) or set on edge as curbing (Figure 5).

Aggregate Uncrushed Stone

Natural aggregate is lightly processed, usually by washing or screening, yielding products suitable for decorative use. Fragments can be either rounded or angular and must be resistant to weathering. Many types of decorative stone aggregate can be used for rock lawns or area covers in virtually unlimited colors. Typically, local materials are used, which limits choice but lowers cost. The aggregate is placed on UV-resistant black, impermeable or semipermeable poly-

Table 1. Typical coverages by size for decorative stone aggregate

Aggregate Type	Size, in.	Size, cm	Depth	Coverage, ft ² /st	Coverage, ft ² /t
Rock	1/4	0.64	2 in. (5.08 cm)	115	126
	1/2	1.27		150	165
	3/4-1	1.91-2.54		120	132
River rock	1-3	2.54-7.62	1 rock	90	100
	3-6	7.62-15.24		60	66
Riprap	1-3	2.54-7.62	1 rock	90	100
	3-8	7.62-20.32		60	66
	6-12	15.24-30.48		30	66
Pea gravel	3/8	0.95	2 in. (5.08 cm)	110	121

Figure 6. Small river rock and volcanic cinder used for a xeriscape lawn

ethylene (most often 4 mils thick) covering a prepared surface treated with weed killer. A wide variety of sizes are used at an application rate of at least 50 kg/m². The rate varies depending on aggregate size and layer thickness (Table 1).

River Rock. River rock constitutes distinctive water-rounded pebbles, cobbles, and boulders commonly used as an area cover (Figure 6). White to gray is typically specified, but other colors are available. River rock most commonly is granite or gneiss, but any durable rock can be used. The rounding usually is done in a river or coastal marine environment. In Pennsylvania, white-to-buff vein quartz is a popular river rock for landscaping (S.W. Berkheiser, Jr., personal communication).

A diverse market has arisen worldwide in rounded stones sold typically by weight (\$0.07 to \$1.65/kg) or bag. The stones are often polished, not always naturally, and may be fairly exotic rock types like jade, but more common stones are also widely sold.

Scoria and Cinder. Scoria or volcanic cinder is a lightweight, vesicular equivalent of basalt (Figure 6) or other basic volcanic rocks. It is used primarily for desert landscaping in the southwestern United States; it is less common elsewhere but is available in most parts of the country. Scoria is sold as either red-to-brown or black-to-gray varieties, but both are otherwise similar. Reddish hues are more popular and, hence, more valuable than other hues

Figure 7. Rock lawn with accent pieces in Belen, New Mexico

Figure 8. Large exposed aggregate panel on a commercial building

(Osburn 1980). The color differences of cinder are a result of the presence (red) or absence (black) of oxygen during volcanic eruption and emplacement.

Fused Argillaceous Rock. Natural fires in North Dakota lignite produce fused interbedded claystone and sandstone (E.C. Murphy, personal communication). In New Mexico, natural coal fires produce a similar material locally called “red dog” (Hoffman 1996). Red baked and fused shale related to coal fires is mined in the northern Powder River basin of Wyoming (Harris 1991; Heffern and Coates 1997). These materials are used as low-quality aggregate in areas lacking better materials or in landscaping.

Crushed Stone

Crushed stone is the most common decorative aggregate and can be produced from virtually any pleasing stone. It is broken mechanically and usually screened before use; larger sizes are often called rubble. Harris (1991) uses the term *decorative aggregate* to describe crushed and sized stone used for landscaping such as area cover, rock lawns, walkways, and borders around plants or gardens (Figure 7). This chapter describes rubble, exposed aggregate, dash, and terrazzo here under crushed stone, although exposed aggregate, dash, and terrazzo are used with a binder such as cement.

Rubble. Rubble consists of large rough stone or blocks produced in quarrying, often as waste, and used for retaining walls, seawalls, bridgework, and landscaping. Only landscaping rubble is considered decorative stone because it is used primarily for its color, texture, or general appearance. In New Mexico, large boulders of pegmatite are used in landscaping as accent pieces (Austin, Barker, and Smith 1990).

Smaller rubble is popular as wall facing in homes and commercial buildings. The primary purpose is aesthetic—it replaces brick or other veneer—but ease of installation, weather resistance, light weight, and ability to bond well with mortar are also important. Rubble can be set in random patterns across 0.05 to 4 m² of exposed rock. Low-density rocks, such as pumice, have several advantages: shipping costs are lower, setting is easier for the stone mason, and few, if any, anchors are required to tie the stone veneer to the wall (Power 1994). In Minnesota, waste rock from processing granite dimension stone, called *grout*, is used as decorative stone, including sawn, split, and even polished slabs (A.M. Johnson, personal communication; Jackson 1997).

Exposed Aggregate. Exposed aggregate is one of the most common methods of using crushed stone (Figure 8). Stith (1970) found the most important properties to be color, hardness, soundness, absorption, shape, size distribution, and impurities.

Many colors and shapes are available, making exposed aggregate compatible with almost any architectural scheme. Color should be uniform and permanent because it is the architect's main criterion. Observation of weathered and fractured outcrops of the proposed aggregate can be useful in determining how the stone will react (Cutcliffe and Dunn 1967). Spalling and other forms of physical deterioration should be noted. The color should vary only slightly, if at all, between weathered and fresh outcrops. Variations in color from exposure to sunlight or weather should be noted to minimize color differences across the faces of a structure (Cutcliffe and Dunn 1967). Color segregation of stone by quarry procedures, blasting, stockpiling, blending, batching, and weathering should be avoided (Cutcliffe and Dunn 1967; Evans 1993).

The ability to cast exposed aggregate in complex shapes and with background coloring (dash) of cement gives the architect great freedom. Aggregate, mixed with white or gray cement in a 2:1 ratio, can be precast into panels or cast in place in walls and floors or walkways, with the aggregate dispersed or concentrated in the facing layer (Stith 1970). The aggregate is exposed by sand blasting, bush hammering, wire brushing, or acid washing the surface of the aggregate/cement mixture (Cutcliffe and Dunn 1967), and then it is sealed.

Dash. Dash, either coarse (for texture) or fine (for color), is added to exposed aggregate, stucco, or concrete. Sand dash is added to stucco and small-scale, exposed-aggregate surfaces for color. Very fine dash is added to concrete or cement as a permanent pigment instead of more expensive mineral pigments that may react with the cement compounds. Well-mixed, nonreactive dash material avoids blotchiness or shade variation common with artificial or mineral pigments and can be used in conjunction with stucco dash or exposed aggregate.

Terrazzo. First produced by the Romans more than 1,500 years ago, terrazzo floors provide quality at low original and maintenance cost and have a very long life. Terrazzo, a mixture of sized, crushed stone, and cement, offers variety in color and design (Figure 9). This mixture is poured into a prepared floor area, hardened, ground smooth, sealed, and polished (Reed 1978;

Figure 9. Terrazzo flooring (polished) at the Dulles International Airport, Washington, D.C. Lighter area near lower center in front of pillar is a reflection off the highly polished surface. Exposed aggregate forms the surface of the pillar.

American Geological Institute 1997). The stone aggregate has low porosity and low absorption. The portion of the terrazzo that needs protection is the portland cement matrix, which is porous and will absorb stains. The primary application of terrazzo is in high-traffic, public areas and buildings. Relatively soft stone—usually limestone, dolostone, or marble—is preferred for terrazzo, but granite is also used. Quality control is paramount during quarrying so that color can be matched across batches. Maintaining consistent color during processing ensures quality, color continuity, and freedom from impurities. The Terrazzo, Tile and Marble Association of Canada (www.ttmac.com) recommends a thin-gauge epoxy or polyacrylate for sealing.

Cut or Dressed Stone

Cut or dressed stone is finished on one or more sides by various methods and is used where uniform surfaces are needed. Typical uses are in walls, monuments, sculptures, waterfalls, or other relatively small, very detailed artistic renderings. Many stones are fashioned into structural or decorative adornments such as capitals, veneers, friezes, cornices, corbels, coping, and ribbing. Nonstructural statuary and art, along with stones too soft or brittle for structural use, are used in some parts of buildings, although in low volume.

Statuary and Objets d'Art

Artists use stone for carving, sculpting, or producing objets d'art (Figure 10). Carvable stone is commonly soft and uniform, such as marble, limestone, soapstone, and alabaster. Some sculptors carve commercial granite and jadeite, though those stones are hard. Color, texture, softness, and the ability to take a polish are important for statuary stone. Carvable stone commands the highest price but accounts for the smallest sales volume of any of the stone categories. Many small firms and artisans cut and polish semiprecious gems and ornamental stone from hard stone such as jade, agate, quartz, jasper, chalcedony, chert, and petrified wood (Burchett and Eversoll 1991), or softer stone such as tuff, talc (soapstone), serpentine (verde antique), marble, travertine, and gypsum (alabaster).

Fireplace Rocks and Hearthstones

Many types of stone are used in fireplaces. Commercial use is restricted to relatively few types compared to the many used by

Figure 10. Renowned sculptor Allan Howser, of Taos, New Mexico, surrounded by statues and rock ready for his chisel

individuals. Although rough stone and aggregate are often used in rustic fireplaces, dressed stone is more typical. Moss rock, flagstone, river rock, scoria, and ashlar are often used as a decorative facing on a fireplace. Argillite or millstock slate is cleaved or rough-finished and used as hearthstones and mantles (Carpenter 1983). Polished travertine is often strengthened with epoxy or cement and is very popular for hearthstones.

Ashlar

Ashlar consists of rectangular, nonuniform stones with at least two smooth parallel sides, set randomly or by design in a wall. The exposed surface of each piece is generally $<0.4 \text{ m}^2$, laid exposing the sawn or naturally smooth face or the rough (broken) face (Figure 4). Ashlar blocks are prepared either from natural slabs that split and fracture into usable shapes or by sawing the required two parallel sides usually about 7 to 15 cm apart. The remaining sides have an attractive broken appearance that, when exposed, is called split-faced ashlar. Natural or sawed blocks are broken in a hydraulic guillotine to assorted sizes, palletized, shipped to the job site, and laid by hand in courses similar to brick.

Monuments and Memorials

Stone is cut and polished for tombstones, historical markers, and similar monuments and memorials. A typical stone used for monuments and memorials is pure white, statuary-grade marble. Monument stone must be hard, take a high polish, and be resistant to weathering. Tombstones are most often one of the varieties of granite.

Tiles and Paving Blocks

Tiles are cut or split stones with one very thin dimension that can be polished (Harris 1991). Typically they are 0.3 m^2 or 0.5 m^2 (12 in. \times 12 in. or 18 in. \times 18 in.) and 10 to 15 mm thick and can be used in many ways on all interior surfaces, including floors and walls (Figure 11). Tiles can be made from many types of stone, but most are slate, granite, marble, limestone, basalt, or tuff. Travertine is also cut into tiles.

Bluestone, slate, and argillite (Carpenter 1983; Power 1983), as decorative stone, are used primarily as flagging and floor tiles, but are also used for sills, stair treads, risers, shower and toilet

Figure 11. Various sizes of flagstone and floor tile composed of red Lyons Sandstone (darker color) of Permian age and other flagstone (lighter color) in stone yard near Lyons, Colorado

Figure 12. Precambrian Vadito schist used as veneer wainscoting in Santa Fe, New Mexico

stalls, and exterior spandrels and facings. They are available in various shades of green, gray, purple, red, black, or variegated. Slate finishes vary from the natural split surface to knife-shaved, sand rubbed, and honed or semipolished (Harben 1990).

Tiles and paving blocks made of tuff generally are called cantera stone but include adoquin, sillar, tufa, tuff, calduro, and others (Kuiper 1988). Most of these are imported to the United States from Mexico.

Veneers and Wall Cladding

A veneer is any rock that can be laid up on a wall. Wall cladding is composed of larger sheets, often filled and polished, of travertine, serpentine (verde antique), marble, and others. Schist (Figure 12), which cleaves along preferred directions, yielding relatively flat stones, is also used.

Miscellaneous Uses

Nonforested areas of the United States use stone in the manner that other areas of the country use wood, such as limestone fenceposts in Kansas (D. A. Grisafe, personal communication). An Internet search reveals many unusual uses for stone around the world, including lamps with bases of rough stone. In some lamps from Bali, even the lamp shade is carved from stone. Intricately carved stone furniture with latticework backs is for sale on Web sites from India. Stone dishes and lidded boxes from ancient cultures can also be purchased, in addition to modern examples, particularly from Southeast Asia. A number of sites sell “healing” stones and are devoted to stone therapy, and soap-shaped deodorant stones are also available. These are but a few examples illustrating the widespread use of stone across the ages.

Synthetic Stone

Cast stone is defined as a refined architectural concrete building unit manufactured to simulate natural cut stone, used in unit masonry applications. The earliest known use of cast stone was in AD 1138 (Cast Stone Institute 2005). Cast stone is a masonry product used as an architectural feature, trim, ornament, or facing for buildings or other structures. Cast stone can be made from white or gray cement, manufactured or natural sands, carefully selected

crushed stone, or well-graded natural gravels and mineral coloring pigments to achieve the desired color and appearance while maintaining durable physical properties that exceed most natural cut building stones. Cast stone is an excellent replacement for natural cut limestone, brownstone, sandstone, bluestone, granite, slate, keystone, travertine, and other natural building stones (Cast Stone Institute 2005). Some cast stone, however, can suffer deleterious effects from prolonged exposure to sunlight (T.P. Dolley, personal communication).

Stone or slag, usually crushed, is the main ingredient in the production of manufactured stone by melting and frothing. Basalt is melted and cast into various forms (Kuzvart, Woller, and Hora 1992). Irregularly shaped boulder- and cobble-sized masses are used as artificial scoria or cinder. Manufactured stone can be used in floor and wall panels.

Crushed marble is combined with a binding polymer, and perhaps a coloring agent, to produce cultured-marble tiles. Ground limestone is mixed with organic resins to produce cultured marble molded into a variety of shapes. Quartz stone is a relatively new product made from pure quartz and polymer binders, creating a countertop or flooring material that has properties similar to those of natural granite.

GEOLOGY AND DISTRIBUTION OF MAJOR DECORATIVE STONES

Hundreds if not thousands of types and varieties of stone are used in the decorative stone industry. The terms used in the stone industry vary widely between countries, the professions involved in the stone industry, and segments of the industry. In Scandinavia, the stone industry differentiates hard stone from soft stone. The latter includes limestones and marble that, if siliceous, may be harder than some igneous rocks like tuff that are called hard (Shadmon 1988). Complete coverage of all local industry classifications is nearly impossible. Consequently, only the dominant commercial rock types are discussed here as an overview.

Granite

Commercial granite, which has a wider meaning than geological petrographic definitions, includes all feldspathic intrusive rock with

visible grains and all metamorphic rocks with gneissic texture. It includes true granite plus other intrusive igneous rocks (Murphy et al. 2002) and their metamorphic equivalents—syenite, monzonite, gabbro, anorthosite, amphibolite, and gneiss. Commercially, dark fine-grained igneous rocks, even of diabase or basalt composition, are often called black granite (Power 1983). Commercial granite, whether light or dark, has high strength and durability and is relatively impervious to water and weathering.

Commercial granite in the United States is quarried at more than 100 sites in 20 states. The dominant companies are Cold Spring Granite, Rock of Ages Corp., and Coggins Granite Industries. Major production centers (Harben 1990) include Georgia (Elberton), North and South Carolina, New York, Massachusetts, Vermont, New Hampshire, Minnesota (St. Cloud), South Dakota, Wisconsin, and Texas (Burnet and Llano counties). Near Elberton, Georgia, about 100 companies quarry and sell granite as rough blocks or finished products such as memorial markers.

Prominent European igneous decorative stones are Scandinavian red granite (rapakivi type in Finland), norite, diabase, and larvikite (an orthoclase-syenite, labradorite). Rossa (red) Aswan granite and red porphyry (*porfido rosso antico*) is produced in Egypt. Green porphyry (*porfido verde antico*) is produced in the Peloponnese region of Greece (Kuzvart 1984). Spain, India, the Republic of South Africa, Australia, and Brazil are also noted sources of granite in the world market.

Pegmatite

Most pegmatites have about the same chemical and mineralogical composition as granite, but pegmatites are typified by very large, interlocking crystals. Most pegmatites have a coarsely crystalline granite composition with abundant quartz and orthoclase feldspar. Other minerals, notably muscovite or white mica, may be abundant. Boulders are preferred to highlight this coarse texture. Many stone or landscaping companies stock large pegmatite boulders, which are moved to the building site by flatbed truck. In Quebec, amazonite pegmatite from Saint-Ludger-de-Milot and Lac Saint-Jean is used for decorative stone aggregate and for small decorative objects (J.-L. Caty, personal communication). Michigan architects surveyed by Johnson (1983) highly favored coarse pegmatite. Although not extensively quarried today, old mines operated when sheet muscovite was mined in the past are inviting to enterprising stone dealers.

Basalt and Traprock

In the western United States, Tertiary and Quaternary basaltic rocks are exposed over thousands of square kilometers. Basalt is fine-grained, hard, tough, dense, and durable. It is composed of pyroxene and calcic plagioclase and is well suited for use as a decorative stone for landscaping.

Traprock is a common term for basaltic dikes or flows. Power (1994) states the correct petrologic term for traprock is diabase or dolerite. When sold as cut building stone, it is commonly called black granite.

Tuff

The main use of tuff is as cantera stone floor tiles and wall cladding (Figure 13). Some Mexican tuff is sculpted into statuary. The tuff varies in color, with pastels predominating. The stone is characterized by many inclusions of large pumice fragments (up to 30%) and phenocrysts, up to 50 mm in diameter, of quartz, biotite, feldspar, magnetite, and rock fragments such as granite or basalt (Kupper 1988). The high porosity of tuff makes this rock suitable where low weight is a factor. In addition, the porosity gives the stone a texture that is visually appealing for rustic application (Figure 14).

Figure 13. Volcanic tuff (cantera stone), cut with a chain saw, was used as the primary building stone at The Lodge (built circa 1930) at Los Alamos, New Mexico. Although containing voids and depressions, the cantera stone hardens somewhat with time to produce a more durable veneer.

Figure 14. Cantera stone blocks used to form a wall at Bandelier National Monument, New Mexico

Marble and Travertine

Geologically, marble is a metamorphosed carbonate and travertine is a sedimentary carbonate deposited from flowing water, usually in a spring system. Commercial marble is an crystalline rock composed predominantly (>50%) of calcite (CaCO_3), dolomite ($\text{CaMg}(\text{CO}_3)_2$), or serpentine ($\text{Mg}_3\text{Si}_2\text{O}_5(\text{OH})_4$). Serpentine with white calcite or dolomite stringers forms verde antique. Commercial marble must take a polish and may include crystalline limestone, travertine, and serpentine in addition to metamorphic carbonate. Crystals range in size from fine (easily polished) to coarse. The ability to take a polish is important, but the color and crystalline character can be more important.

Limestone, Dolostone, and Marble

Carbonate rocks, usually marine in origin, are found in many parts of the United States and many other nations. The Bloomington–Bedford District of southern Indiana has produced a well-known dimension limestone (commonly called Indiana Limestone) for more than a century. Limestone and dolostone are usually gray, but can be white, buff, tan, or black. White marble is composed of nearly pure calcite. Dolostone is composed predominantly of dolomite. Mineral impurities that darken limestone and dolostone include iron carbonates, iron oxide, iron sulfide, chert, silica, clay, graphite, and carbonaceous matter (Power 1994). Crystallinity, bed thickness, ease of polishing (3 to 3.4 on the Mohs hardness scale), and the presence of fossils, stylolites, or other textures and structures make limestone and dolostone attractive decorative stones. Bedding can vary from thin to massive and is important in determining the end use of commercial marble and travertine. Limestone imported into the United States comes primarily from Spain and France.

The Georgia Marble Company in Georgia and the Vermont Marble Company in Vermont quarry the bulk of U.S. commercial marble production. Marble, particularly white marble, is commonly crushed and sized and sold in lots ranging from carloads to bags of <45 kg. White marble from Georgia (Power 1994) and varicolored travertine from New Mexico (Austin and Barker 1990) are premium decorative stones. The Yule quarry in Gunnison County, Colorado, which supplied white marble for the Lincoln and Jefferson Memorials in Washington, D.C., has recently operated intermittently after being closed for many years. Marble imports come principally into the United States from Italy, Portugal, Spain, and Turkey.

Travertine

Commercial travertine is hard, dense to vuggy, finely crystalline, compact, massive to concretionary or fibrous limestone that takes a polish (Austin and Barker 1990). Impurities in travertine impart colors ranging from white to pink, red, tan, yellow, green, gold, brown, or black. Variations in impurities can cause multicolor banding of layered travertine. Travertine may be called tufa (within the industry; tuff is used to describe cantera or volcanic tuff, but never travertine), calcareous sinter, marble, Mexican onyx, or onyx marble. New Mexico Travertine produces most of the domestic travertine (Barker, Austin, and Sivits 1996).

Sandstone and Conglomerate

Sandstone suitable for cutting, flagging, and curbing has been produced worldwide for thousands of years. Commercial sandstone consists of both sandstone and siltstone. Color variations are due largely to iron oxide. Moss rock is a popular sandstone found in many areas as loose fieldstone on surface outcrops. Picture rock is sandstone that exhibits complex color (liesegang) banding from variations in weathering and which is sold as slabs cut to simulate landscape paintings.

Slate, Schist, and Gneiss

Slate is a fine-grained metamorphic rock with pronounced, relatively smooth, and flat cleavage surfaces that is used mainly for roofing. Stair treads, floor tile, flagging, wainscoting, trim, chalkboards, billiard and laboratory tables, plaques, and signs are also produced. Slate can be purple, gray or black (reduced), red or green (oxidized), or mottled. These colors can alter or bleach on exposure (called semiweathering), but roofing slate should have permanent colors (called unfading) or at least alter evenly to a pleasing shade and be from the same lot. Most slate is initially split by hand from

quarry blocks (Sweet 1990) with further punching by foot treadles and machine shaping.

Slate production in the United States is concentrated in New York, Vermont, Virginia, and Pennsylvania, where it is centered at Pen Argyl and Slatedale. Slate production techniques have changed little with time. Quarrying must be done slowly with little blasting because it would split the slate. Wire and chain saws are also used. Cold weather limits the quarrying season in many places; the stone is ruined if it is freeze-thawed while in large blocks, so none can be quarried ahead without careful storage. Slate is still largely hand split and punched with foot-driven treadles. Because of the assistance of nature in prying weakened surfaces apart by alternating freezing and thawing, flagstone quarries tend to be small and close to the surface.

Sale of slate in the United States is particularly strong in the South, Southwest, and California (Harben 1990) because of its resistance to color change over years in direct sunlight. Slate is growing more important in world markets for its natural unpolished appearance, nonslippery and multicolored durable surfaces, and relatively low price (Vagt 2003).

Quartzite

Quartzite is metamorphosed quartz sandstone that breaks through the grains rather than around them. Commercial quartzite is a hard siliceous rock commonly white to light-gray to bluish-gray or pinkish. Gneiss is often marketed as quartzite. In Virginia, thin-bedded to massive quartzite of the Cambrian Weverton Formation has been quarried since 1893 (Sweet 1990).

Quartzite is marketed for flagstone, veneer facing stone, and other decorative uses. Fern stone is quartzite containing dendritic limonite along bedding planes. Idaho also produces quartzite used as both flagging and building stone.

PRODUCTION

Decorative stone operations range from very small to very large. Many large quarries producing dimension or building stone also produce large quantities of waste rock, although their preferred output is large, sound, rectangular blocks. This waste material is normally crushed to aggregate, screened, and sold as decorative stone. It may alternatively be processed into ashlar (Figure 15). Aggregate quarries produce rock that can be used as higher-value landscaping stone as easily as lower-value concrete aggregate. Demand, appearance, and cost of the stone are most commonly the deciding factors in the choice between these two alternatives.

A number of finishes can be applied to a stone on an edge (E), a surface (S), or both (B):

- Natural cleft—natural, nonuniform finish (S)
- Sawn—dull, smooth finish created by a diamond or wire saw (E/S/B)
- Split—split with the natural grain (E/S)
- Honed—smooth, formal look, no shine (E/S/B)
- Polished—smooth, mirror finish (E/S/B)
- Flamed—slightly pebbled, medium relief (E/S/B)
- Sandblasted—slightly textured finish, light relief (E/S/B)
- Rocked—hand-cut, chiseled finish, heavy relief (E)
- Bush hammered—small pyramidal indentations, medium relief (E)
- Tumbled—rotated in a drum; rocks semirounded (B)

Only two producers are active at this time. Georgia Marble produces only their white marbles, which under French ownership

Figure 15. Breaking and palletizing ashlar from dimension stone waste at New Mexico Travertine in Belen, New Mexico

will expand over the next 5 years using imported stone. New Mexico Travertine produces several colors of travertine from its quarry but has expanded to use more than 12 limestones from other domestic quarries. Tennessee Marble Company produces tiles and slabs but primarily markets the stone for cut-to-size projects and has limited access to stones other than Tennessee pink, which is difficult to produce and is limited in slab size (Matthews 2002).

Quarrying

Quarrying decorative stone uses the same general techniques used in the production of other types of stone, but details are adjusted depending on the desired finished product. For example, blasting is minimized using small charges of low-velocity explosives for slab blocks. Stone quarries use diamond wire saws, belt saws, chain saws, and air wedges that allow rapid, more accurate quarrying and produce thinner products than in the past. Great care and considerable hand dressing (Figure 16) are necessary for high-quality wall capstone, flagstone, or slate. Accent pieces used in landscaping, such as large pegmatite boulders, require preservation of the coarsely crystalline surface during transport to the final site. Cranes may be needed to lift pieces, and padding is used to prevent damage in transit. Contrast this to the production of crushed stone, which requires almost no protection.

Stratification in rock produces zones of weakness called rift by producers. These are important because they determine the direction in which the stone splits most easily. Spacing of the rift determines the thickness of the quarried layer. Bed seams, joints, cutters, reeds, and runs are additional terms used in the sandstone industry to describe other natural planes or directions in which the stone splits or can be cut (Bowles and Barton 1963).

Processing

By the early 1900s, the muscle power of earlier ages had given way to steam, electricity, and compressed air. In recent years, carbides and diamonds for cutting and higher grade steels for drills have allowed for more efficient cutting of stone, but the basic equipment was similar to that of the past. Since the Browning torch was developed, it has been widely used in the granite industry and has revolutionized channel cutting (Meade 1986a). Channel cutting with

Figure 16. Limestone capstone being carefully hand-dressed at the finishing plant of New Mexico Travertine, Belen, New Mexico

diamond-studded belt saws is doing the same to limestone and marble production (Harben 1990). High-pressure water jets are also being used to quarry granite in North Carolina.

Automation that allows affordable production is being introduced rapidly, but much waste is still produced, leading to coproducts. Products include tiles and other decorative pieces such as kitchen counters, table or desk tops, bathroom counters and basins, and fireplace mantels. The trend is toward thinner slabs, specialty surfaces (polished or flame textured), and new applications such as coordinated lines of furniture in homes. Production of large volumes of crushed stone is ensured by modern drilling equipment, blasting techniques, and crushing and processing machinery.

SPECIFICATIONS

Formal specifications exist through the Marble Institute of America for most stones used in the dimension stone industry. Specifications are less developed in the decorative stone industry, where color and texture are of principal importance, along with the surface treatment used. The ability to be split into flat slabs is important in the production of flagstone, of less importance in fieldstone and moss rock, and of no importance for river rock.

Strength, porosity, adsorption, and durability are important in some decorative stone end uses and of little importance in others. Durability and strength are significant in crushed stone used for some decorative purposes, such as terrazzo and exposed aggregate (Ault 1989). The Aggregates and Dimension Stone chapters in this book cover physical properties in detail.

Flagstone

Irregularities on a flagstone wear surface must be <1 cm in height (Harris 1991) to minimize tripping. A standard test for abrasion resistance of stone subjected to foot traffic is given in American Society for Testing and Materials (ASTM) Standard C241.

Tiles and Paving Blocks

Slate for floor tiles sold in the United States comes in four basic square or rectangular sizes from 15 × 15 to 46 × 46 cm (Figure 17). Size is limited only by the curvature of foliation, which can cause tripping in tiles more than 1 m across. Tile thickness varies from

Figure 17. Processing line for square floor tiles at New Mexico Travertine

6 mm for light-duty and housing use to 9 mm for heavy-duty use in public areas (Harben 1990). Flexure testing of slate is covered by ASTM C120. A minimum abrasion resistance (ASTM C241) of 10 is required for carbonate floor tile. Where two or more marbles are combined, there should be a maximum difference of 5 points of abrasion resistance. For stairways, floors, and platforms subject to heavy foot traffic, a minimum abrasion resistance of 12 is recommended.

Exposed Aggregate

In general, tests for exposed aggregate are variations of those used for cement and road building or construction-aggregate end uses. Standard evaluation techniques for such end uses may have severe shortcomings when applied to exposed aggregate. Highway service records, acceptance tests, and government ratings of stone do not correlate with its quality as exposed aggregate (Cutcliffe and Dunn 1967).

Hardness is determined by Los Angeles abrasion, ASTM, or Micro-Deval tests. The aggregate should be hard enough to minimize replacement of faulty exposed aggregate because repair costs are extremely high, if repair is possible at all (Cutcliffe and Dunn 1967; Stith 1970). Abrasion resistance is less significant in exposed aggregate, but softness or brittleness may cause excessive fines during batching (Cutcliffe and Dunn 1967).

Soundness is the main criterion that determines the durability of exposed aggregate during temperature and humidity cycles, weathering, and erosion. Several sides of an exposed aggregate particle often are not encased in cement, making poor-quality stone very susceptible to weathering. A variety of tests involving freeze-thaw cycling and exposure to solutions are applied to exposed aggregate as discussed by Stith (1970) and Cutcliffe and Dunn (1967).

Water absorption should be <1.5% because high absorption promotes weathering and staining (Shergold 1954; Stith 1970). Average pore space and percentage saturation also influence soundness. Completely saturated rocks, small pores, and capillaries are more deleterious than larger, better-drained pores (Verbeck and Landgren 1960; Yedlosky and Dean 1961; Stith 1970).

Particle shape and size distribution are less important factors for exposed aggregate. The two main criteria are few thin or platy particles and minimal dust or fines. Impurities to avoid are shale, clay, iron sulfides and pyrite, chert, gypsum, bituminous materials,

dolomite, limestone, or any reactive material >1% by weight (Cutcliffe and Dunn 1967; Stith 1970).

Dash

Dash is fine-grained (up to 9 mm) exposed aggregate, and the basic principles and specifications previously described for exposed aggregate apply. Stone grains as small as 1.5 mm are used as concrete block facing (Ladoo and Myers 1951).

Terrazzo

Aggregates for terrazzo use are tested by methods applicable to aggregates for other uses. These include ASTM Standards C33, C88, C131; Los Angeles abrasion; and sodium sulfate tests. Terrazzo is essentially exposed aggregate with only one side exposed, so the criteria previously described for exposed aggregate generally apply. Specifications and data on terrazzo are available from the Terrazzo, Tile and Marble Association of Canada or the National Terrazzo and Mosaic Association.

Veneer and Cladding

Modern use of interior decorative stone as veneers and cladding does not require the high ASTM standards for compressive or flexural strength called for in structural stone. Exterior veneer and cladding stone is hung, using a variety of support and anchor systems, to the structural wall behind. Stone that meets the minimum ASTM criteria for flexural strength, modulus of rupture, and density is usually suitable for exterior veneer.

The standard specification for marble dimension stone (exterior) is ASTM Standard C503. Marble in this context includes calcite, dolostone, travertine, and serpentine. Marble for exterior use must be sound and free of spell cracks, open seams, pits, or other defects that would affect its strength, durability, or appearance. Molded, cast, or artificially aggregated units are discussed under the section on Synthetic Stone in this chapter.

Cantera Stone

The criteria established by ASTM for cantera (consolidated volcanic tuff) stone are as follows: bulk specific gravity (C97), 1.336 to 1.88; absorption (C97), 9.9% to 22%; modulus of rupture (C99), 435 to 1,520 psi; compressive strength (C170), 1,800 to 9,960 psi; and an abrasive hardness (C501) of 3.3 (Kuiper 1988).

ECONOMIC FACTORS

The decorative stone industry tends to be vertically integrated in the United States, although a dealer/distributor network is also in place. Many producers market both through their own sales operation and through various representatives. This is due in part to the desire of clients to view the stone before purchase. Developers of large projects often visit the quarry, but it is often advantageous to have examples of the stone available regionally at distributors.

The decision to use a particular stone in a project is made by architects who, as a group, are the greatest single influence on demand in the decorative stone industry. The reputation and trade name of the stone are the principal factors rather than test results used by architects to determine durability. Architects rated factors affecting their choice of stone (Johnson 1983) from most important to least as follows: (1) appearance (overwhelmingly), (2) durability, (3) cost, and (4) availability. Appearance of stone depends on color, texture, and uniformity. Limestone was the most frequently selected stone with granite second, but exposed aggregate panels were preferred for small commercial buildings. Stone is specified often for government buildings, sometimes for churches, and increasingly for commercial or residential structures.

Costs

Decorative stone ranges from a moderate cost, high-bulk commodity to a high cost, low-bulk one. Crushed stone for landscaping (ranging from \$15 to \$90/t) is an example of the former, whereas stone for sculpture (perhaps \$6,000 for a large block of Carrara marble) represents the latter. Decorative stone often commands a higher price than identical stone used where aesthetics are not considered.

In 2005, costs for decorative stone in Tucson, Arizona, ranged from \$22 to \$42/t for sized, bulk, landscaping materials in various colors. Tumbled stone was \$88/t and standard boulders were about \$0.18/kg. Specialty boulders ranged up to \$0.88/kg. Transport was \$15 to \$70 per load in the greater Tucson area with large orders trucked free to the jobsite (K. Santini, personal communication).

Transportation

All major forms of transport are used for decorative stone. Truck transport of aggregate (86%) predominates over rail (6%) or inland/coastal water transport (barge 2% and lake <1%), whereas sea transport (<1%) is least common (Anon. 1988). Any transport by water, barge, or ship is the lowest cost. Truck transport is very effective, though usually more costly per unit shipped, because of flexibility and orientation toward individual irregular shipments and low capital outlay (Hayes 1991). The stone is shipped in bulk or palletized (Figure 18) and is loaded onto the truck at the production site to be carried directly to the end-use site with no intermediate handling. Delivery by truck is prompt, and damage is minimal even for polished or slabbed stone. In contrast, rail transport may cost more because it is oriented to large predictable shipments, is capital intensive, and has high fixed costs. High railcar coupling speeds may damage more stone than road vibration during truck haulage. Rail rates often are set according to the finish rather than simply by the type of stone. Timing is important because most consumers need rapid delivery once a decorative stone is ordered. Distribution yards closer to consumers than production facilities are often used for flexibility and rapid delivery (Hayes 1991).

In Michigan (Johnson 1983) in the early 1980s, transport costs ranged from 20% to 100% more for highly finished stone than for the same stone when unfinished, rough, split, or sawn. Crushed stone transport cost was only about 40% of that for unfinished stone. Shipping of decorative stone on the Great Lakes was not readily available then, although its cost would have been about 10% of rail rates. Lake transport was reserved for large volumes from established producers with regular shipments, such as coal or iron ore (Johnson 1983).

Most factors applicable to construction aggregate transport apply to decorative aggregate. Decorative stone aggregate carries significantly more value than construction aggregate, even if they are the same rock, so higher transport costs are justified. Decorative stone includes a wide variety of products requiring transportation. Although much stone is used locally, certain segments of this market will support higher cost transport offshore and worldwide. Decorative stone is often sold in relatively small lots, so bulk transport cost advantages cannot often be realized, although they are substantial if the shipment is large.

End uses of decorative aggregate such as landscaping rock are the most sensitive to transport cost and thus travel the least distance, although this distance can be significant. Aggregate has been imported into the United States (Timmons and Harben 1987) to areas accessible to ships such as the eastern, Gulf, and southeastern coasts of the United States, and large portions of the Midwest by barge. This is particularly true for low-volume retail sales where small lots may be shipped long distances because the per-ton retail

Figure 18. Various rock types sorted by size, shape, and surface coating (such as moss rock); palletized, and ready for shipment by truck in New Mexico Travertine's yard

value is high. Polished or slabbed decorative stone, a high-value commodity, can be shipped any distance if well protected. In contrast, decorative aggregate is resistant to exposure and shock and needs minimal protection during transport.

Substitutes

All decorative stones have competition from substitute materials, and more are appearing. Examples include concrete, enameled porcelain, stainless steel, aluminum, brick, plastic, synthetic stone, crushed glass and slag, and recycled materials. The aesthetic appeal, prestige, and durability of stone are exceeded by few substitutes. For this reason, substitutes simulate stone, often at lower cost. Stone substitutes are often designed as prefabricated modules or precast panels, as recommended for much of the potential decorative stone in Michigan (Bourque and Associates 1999). Some decorative stone such as terrazzo or exposed aggregate is also used in panels.

TARIFFS AND DEPLETION ALLOWANCES

Complex tariffs on imported dimension stone also apply to dimension stone used as decorative stone. In the United States, the tariffs in 2003 varied from free to 6.5% for Normal Trade Relations (NTR) status according to type, size, value, and degree of preparation (Dolley 2005). Tariffs on crushed or rough stone, including that used for decorative purposes, are 3.0% ad valorem (Dolley 2005).

In the United States, the depletion allowance for domestic or foreign decorative stone depends on the form of the stone and its end use. For dimension stone, it is 14%. For slate used or sold as sintered or burned lightweight aggregate, it is 7.5%. For stone used for rubble and other non structural purposes, the depletion allowance is 5%.

MARKETS AND TRENDS

The use of steel, glass, aluminum, plastic, and reinforced concrete made stone non essential in construction and caused a long-term decline in use of large structural blocks (Johnson 1983). Sales of stone for exterior paving and curbing have decreased because of increased use of asphalt and concrete. In the last few decades, the beauty, heat and sound insulation, and permanence of stone have led to its use for exterior cladding (sheets or panels) of many commercial buildings (Hora 1994).

Stone acceptance and usage in the United States have grown in recent years. In Europe, use of decorative and roughly dressed stone dropped from 50% to 0.25% relative to crushed stone during the 20th century (Kuzvar 1984). Recently the aesthetic appeal of stone and the development of thinner stone in lightweight panels and frames have offset this to a degree (Johnson 1983) and have increased the use of stone veneers and cladding. Thin-stone slab applications are favored by architects because of lower cost relative to glass and steel (Sweet 1990). Dimension stone is being used more commonly in the residential markets. Improved quarrying, finishing, and handling technology, as well as greater variety of stone and the rising cost of alternative construction materials, are among the factors that suggest a continuing increase in demand for dimension stone during the next 5 to 10 years (Dolley 2005). Domestic crushed stone production appears to be stable or increasing slightly. While crushed stone free on board (f.o.b.) prices are not expected to increase significantly, the delivered prices are expected to increase, especially in and near metropolitan areas, mainly because more aggregates are being transported longer distances (Tepordei 2005).

Veneer style has shifted to smaller pieces of stone assembled in panels for unit construction, giving a cubic look, particularly for granite buildings. Extensive engineering and testing led to precasting of stone and concrete panels, epoxy bonding of finished stone panels before installation on site, and most recently, bonding of ultra-thin stone veneer to expanded aluminum backing (Meade 1986b). Use of stone increased for decorative interiors with various shades and colors of marble in lobbies and foyers. Residential use of thin stone tiles and countertops, particularly granite, has increased. Decorative stone panels and tiles made from agglomerated stone such as Chilean lapis are bonded into tiles for high-contrast colored trim (L.P. Meade, personal communication). Over time, taste in stone architecture changes and some stones fall out of favor, such as the brownstone fronts once popular on urban residences (Ladoo and Myers 1951).

The trend in North America is for specialized use of stone for architectural purposes. The trend in stone use is away from blocks and toward veneer and cladding in larger thin panels that, depending on stone type, may need to be backed by glass fiber/epoxy or other strengtheners. Wider spans may need to be thicker or use special anchors depending on wind load or other factors. A trend in architecture is toward smaller, thinner preassembled stone panels set in larger panels for rapid installation onto steel frameworks or exterior walls to yield a look as if built with large stone blocks.

The broader residential market that uses a wider variety of stone is growing, particularly in the Southwest, but demand is not great enough to create demand for all quarry waste. This contrasts with Italy, where virtually all stone quarried is used, so U.S. costs remain higher for stone and also for fabrication. The European participation in the Marble Institute of America shows that the U.S. market is viable for importers. Multinational participation in the U.S. stone industry is helping establish acceptable standards for suspension systems and artificial supports. The U.S. stone industry carries much higher product liability, and environmental, safety, and health costs, compared to foreign producers (Meade 1986a).

The stone industry remains labor intensive, which limits markets for relatively costly U.S. stone. Technology improvements, particularly widespread diamond (Harben 1990) or flame cutting, partly offset this. Improvements in mechanical fasteners and cements have fostered the decorative stone panel market, which is also being standardized to improve competitiveness. Increased panel sales means increased sales of exposed aggregate, often turning quarry waste into a product. Chemical treatment to increase

durability of stone is making a wider variety of stone types available (Johnson 1983).

Zoning and alternative land use are constant concerns of the stone industry. Federal agencies and sometimes state or local agencies regulate stone quarries and sand and gravel operations. The decorative stone industry in the United States is subject to the same safety, health, and environmental pressures and regulations as the aggregate and dimension stone industries. Much decorative stone is produced as a coproduct of urban stone quarries that are under extreme pressure to relocate farther from growing population centers and to impact less on wetlands. Many inoperative quarries are being converted into scenic and high-value commercial and residential developments. Shortages of aggregate in most urban areas are likely because of local zoning restrictions and land development alternatives. The stone industry will continue to be concerned with environmental restrictions and safety factors.

Matthews (2002) characterized and summarized trends in the North American dimension stone and the largely derivative decorative stone markets as follows:

- Domestic stone production is unable to meet increasing demand; >97% is imported.
- Besides Italy, Turkey and Mexico are supplying stone.
- Per capita use of stone is less than half that of Europe, so market growth is likely.
- Increased stone use during the 1990s was in residential fireplaces (stone), bath rooms and entryways (tile), and kitchen countertops (granite).
- Colors in demand are beige, yellow, and white; green and black are still high in demand.
- Limestone is the stone of choice, and buyers want honed, sandblasted, water jet, flamed, or antique finishes. Granite and marble are declining in market share against limestone. Slate, quartzite, and sandstone demand is increasing. Cross-cut travertine will lead demand. Indiana limestone, available only in buff-beige or gray, will decline.
- The latest finish for granite is water-blast, which is evenly textured while maintaining color, and will partly replace flamed granite. Textured finishes that do not alter the characteristics or color of the stone are preferred.
- The demand for tile, including natural stone tile and tile decorative accessories is displacing ceramics and hard floor coverings, the dominant domestic market. The carpet industry is competing by consolidating carpet sales with ceramic and stone. This will lead to increased demand for natural stone tiles.
- Stone marketing is often domestic and local in scope. Most producers are regional and neither promote nor sell nationally. They do not use outside distribution channels.
- The lack of vertical integration in stone production and marketing is eroding. Many fabricators are becoming installers and importers, making stone use more affordable. Many contractors or developers directly import stone.
- Producers typically operate a quarry serving a small fabrication plant capable of producing only cubical work sold to contractors for commercial or residential cladding. Very few producers are capable of producing tiles, slab, or shapes.
- Countertops are the largest use of granite, which now competes with synthetic and laminate tops. As the price of synthetics increases and that of granite decreases, granite use in kitchens will dramatically increase.

- The do-it-yourself market is significant.
- Local craftsmanship will rise as stone demand grows. The shortage of qualified stone professionals, a sore spot with consumers, is temporarily being filled mainly by workers from Mexico. Fabricators and installers must continually train workers to ensure quality installations that foster market growth.
- New domestic trade shows for hard surfaces are promoting flooring and countertops that include stone.
- Buyers want delivered-to-their-door prices from local companies rather than ex-factory imports with their price and timing uncertainties.
- Buyers will pay a premium for quicker service and delivery of stone, preferably in a designed package.

ACKNOWLEDGMENTS

Much of the knowledge in this chapter of the various uses of decorative stone was gained through conversations and other communications with many professional and industrial personnel. It is impossible to thank all these individuals, but many are mentioned in the text. They gave examples that shaped the thinking on decorative stone. Special thanks to Ken Santini for aggregate cost and aggregate areal coverage data. Thomas Dolley of the U.S. Geological Survey reviewed the manuscript, as did Jim Deal, Tim Lardner, and Jim Lardner of New Mexico Travertine.

Dimension Stone

L. Mead and G.S. Austin

Stone is considered by many to be the premium material in all kinds of construction. Its use dates to the dawn of civilization, and only buildings made of stone have survived from ancient times. Although the use of stone relative to other materials declined during the latter half of the 20th century and reached a low point in the 1970s, there was a strong resurgence in the use of stone in construction during the 1990s. This is most likely the result of new techniques for producing stone, a greater recognition of its beauty and durability, and greater affluence among consumers. The attraction of stone is confirmed by the many attempts to simulate it in synthetic materials. Today, natural stone is considered by many to be the ultimate in aesthetic appeal, durability, and ease of maintenance.

During the past decade, production and consumption of dimension stone has increased dramatically worldwide. Figure 1 shows a dimension stone quarry recently opened in the Dominican Republic, exemplifying the dramatic increase in global stone production. The U.S. Geological Survey (USGS) reports that U.S. production and consumption of domestic dimension stone in 2003 had a value of \$236 million. For the same period, the value of imported stone was \$1.46 billion. Similar figures for 1992 show the value of domestic dimension stone consumption was \$198 million, with an additional \$404 million worth of dimension stone imported from various worldwide sources.

Meaningful statistics on dimension stone are difficult to acquire. Although the finished piece of stone is a highly value-added product, stone can be sold as rough blocks, sawed slabs, or finished product. The same piece of stone can therefore be sold and reported three or more times. Furthermore, although the quantity of stone is most commonly reported in tons, stone cladding is more often sold by the surface area and at the same price for different thicknesses. By any measure, however, the production and consumption of dimension stone has increased dramatically during the past decade. A significant indication of the resurgence of stone has been the increased circulation of new trade publications and the increased membership in the stone trade organizations.

DEFINITIONS

In this chapter, the term *dimension stone* refers to stone that is finished to specific dimensions and shapes. Most commonly it is quarried in large rectangular blocks, which are then sawed into slabs for further finishing, and used in buildings, monuments, furniture, industrial applications, and other uses. Other stone, sold as field-

Courtesy of Geomapping/Technographics.

Figure 1. White marble quarry in the Dominican Republic

stone, flagging, rubble, and other similar names, is sold in either natural or broken sizes and shapes that are sorted into size ranges but not finished or dressed to specific dimensions. These types of stone can be used for building, paving, decorative, or other purposes.

The American Society for Testing and Materials (ASTM) and the USGS include both of these groups as dimension stone. Nonetheless, the distinction seems important. The dimension stone industry as defined here is highly sophisticated, using complex, often computerized equipment and large quantities of industrial diamonds and other abrasives. This portion of the business is capital intensive and becoming more so. The production of stone that is not cut or finished to specific dimensions remains a less sophisticated, more labor-intensive industry. The equipment used is simpler—drills, front-end loaders, and trucks—and the products are hand picked and sorted. Common to both, however, are sophisticated marketing techniques. Although family-owned operations serving local markets produce some nondimension building stones, others are marketed nationally and/or internationally.

Three of the most widely distributed trade magazines reflect the distinction. *Stone* (formerly *Dimensional Stone*, Collingswood, New Jersey, www.stone@ashlee.com) covers dimension stone as defined here, with articles on new machinery, production techniques, market trends, and similar information. An annual directory and buyer's guide is published every December. *Stone World* (Paramount, New Jersey, www.stoneworld.com) also is devoted to dimension stone, publishing similar articles, with a buyer's guide published every November. *Building Stone Magazine* (Building Stone Institute, Purdys, New York, <http://www.buildingstoneinstitute.org/publications.htm>) covers the full range of building stones including rubble, flagging, and fieldstone. Its emphasis is more on the end product (finished buildings, homes, etc.) than techniques. Much of the advertising in this magazine is for stone that is not quarried in blocks and dressed to specific size. All three magazines have extensive advertiser indices and offer reader services to their advertisers.

There is no simple way to logically organize dimension and building stone into a neat outline. Building stone includes both dressed and undressed stone, so dimension stone can be considered a subset of building stone. Dimension stone (as defined here) can be used for buildings, furniture, rolling mills, and other industrial uses, so building stone can be considered a subset of dimension stone. In this chapter, dimension and building stone are subdivided into two classes:

1. **Dimension:** Stone that is cut and finished to specified sizes and shapes, which can be used for buildings, monuments, paving, furniture, and decorative objects. Sometimes called cut stone, it is typically quarried in rectangular blocks, then sawed and finished to specification.
2. **Building:** Stone that is sold in natural or broken sizes and shapes, which can be used for building, paving, rough construction, landscaping, and erosion control. It can be collected from the surface, be broken out of a quarry, or be the by-product of a block quarry. It is typically hand sorted into ranges of sizes and shapes.

Both types of stone can be used in building. When so used, broken stone will produce an irregular, or natural, appearance. Horizontal lines will be wavy. Cut stone used in building will produce a regular or geometric appearance. Horizontal lines will be straight. Many consider cut stone to be the only true dimension stone.

Dimension and building stone are also classified lithologically, which can create great confusion among geologists and engineers. The dimension stone industry is one of the oldest in the world, and many of its terms predate the advent of modern geology. For example, the *Oxford English Dictionary* (2nd edition, s.v. "Marble") lists five columns of definitions for marble, many of which have no relationship to a modern geologic definition. In Italy, marble includes all hard stone that is capable of taking a polish, including granite and other rock types. The ASTM committee on dimension stone has gradually modified its definitions to bring them more into line with modern geology, but large disparities remain. Most commercial retailers dealing in stone are not well versed in modern scientific definitions, nor is there any compelling reason why they should be. It is important for the geologist or engineer who becomes involved with the commercial stone business to learn the trade language.

Stone Sold and Used in Natural or Broken Sizes

This category includes all stone that is gathered from the surface, broken out of the quarry, or is an undressed by-product from a block quarry. In building construction, it produces a natural look

and in today's market is especially popular in homes and small commercial buildings. Some of this stone is produced and sold locally by small operations, but much is distributed nationally.

Fieldstone

Gathered from the surface, fieldstone is used to make stone walls, fireplaces, and similar structures. Dating back to antiquity, it was an important building material in early America. Although rock vendors may sell fieldstone, there is no generally accepted commercial connotation as to size, shape, or rock type except that it can be set by hand.

Rough Construction and Jetty Stone

Large blocks of rough-hewn granite or other stone have long been used in such structures as retaining walls, seawalls, and bridge work. For use in these applications, the stone must resist weathering and erosion and break naturally into rectangular shapes that are easily set. Granite fits these requirements admirably and is the most widely used stone for this purpose. Other good sources are waste or rejected blocks from dimension stone quarries.

Rubble

Smaller sizes of broken stone are very popular as wall-facing material in building construction, both for homes and small commercial buildings. The primary purpose is aesthetic—rubble replaces brick or other veneer—but ease of setting, weather resistance, light weight, and the ability to bond well to mortar are also important. With a minimum of capital investment by small operators, the stone can be produced as a by-product from other stone operations or from small pits. The only requirements are that it is marketable and that it can be transported easily and cheaply to market.

Because of the ease of production, there are many small producers supplying local markets. In 2003, some 132 companies produced dimension stone in 176 quarries located in 34 U.S. states (T.P. Dolley, personal communication). Some of the sellers quarry their own stone, but some also contract for the exclusive right to sell stone produced by a small operator in return for supplying advertising and distribution services.

The rock types advertised by the Building Stone Institute include all the standard dimension stone types as well as obsidian (which is actually pumice) and specialty stones. Some of these have national distribution.

Rubble is set in random patterns and the sizes of pieces range from about 0.05 to 0.5 m² of exposed rock. A few years ago, slabs of thin-bedded natural flagstone were commonly used with the bed set parallel to the wall, but recently the three-dimensional effect has become more popular, and natural flagstones are more commonly set in courses with the bed perpendicular to the wall (see next section). Nonetheless, slab-shaped rocks have an advantage in that they cover more surface with less volume and weight. Low-density rocks such as pumice and other porous rock have several advantages. Shipping costs are lower, setting is easier for the stone mason, and fewer or no anchors are required to tie the stone veneer to the wall. The wall, however, can be weaker.

Flagstone

Flagstone consists of thin slabs of stone used as paving. Slate and fine-grained sandstone are the most popular rock types, but any naturally fissile stone can be used, provided it has sufficient abrasion resistance.

Flagstone slabs are generally 25 to 75 mm thick, but thinner slabs can be used where they are placed on an exceptionally firm base and subjected to only light traffic. Flagstone can be sawed into

rectangular shapes or can be produced in naturally irregular shapes. It can be sold in either cut or broken sizes. The largest production of cut flagstone is from bluestone and slate. Much slate flagstone is from quarry blocks that are not suitable for mill stock or other higher-priced products. Random-shaped flagging is done by small producers for local markets. A standard for abrasion resistance of stone subjected to foot traffic is given in ASTM C241 (Table 1).

Paving Blocks

Small rectangular blocks of granite were formerly used to pave roads, docks, freight yards, and other areas subjected to heavy traffic. This market has all but disappeared, owing in part to the substitution of rubber tires for steel rim wheels. A small amount of granite is used for ornamental paving, and, in a similar application, a large amount of granite is used to cover slopes near bridge abutments and other areas where slope stability and erosion is a problem.

Stone Cut to Size

This group includes all stone that is cut to specific dimensions on at least two sides. Most of it is quarried as large, rectangular blocks that are sawed into slabs and pieces of the desired dimension.

Dimension Stone

Dimension stone includes all building stone that is cut to specific dimensions on all sides. The surface can be textured, smoothed, or polished, but is always controlled and finished to specifications. Dimension stone can be quarried and finished by a single producer or it can be finished by manufacturers who purchase quarry blocks or sawed slabs from a quarrier.

Accurate data on production of cut dimension stone are difficult to obtain. The USGS publishes annual reports on the production and value of various lithologies, but these data are deceptive because they are reported in mass units, whereas most cut stone used in construction is sold by volume. The production and finishing of cut stone is essentially a value-added business where the actual cost of raw material is a small portion of total cost.

Specifications for dimension stone are stricter than for other categories of building stone. The most important physical tests as specified by ASTM are listed in Table 1. In addition to these tests, the coefficient of expansion and thermal conductivity are important in some applications.

Most dimension stone is used as non-load bearing curtain walls, or veneer. In modern architecture, the use of natural stone as structural members in buildings is almost nonexistent, but columns, lintels, and other structural members can be faced with natural stone. The stone is hung using one of many systems on the market.

Stone panels ranging in thickness from about 20 to 100 mm are set as a veneer with horizontal supports at each floor and appropriate anchors to the structural wall behind. The load-bearing requirements of the stone are therefore limited to self-support for a floor height despite the rather high requirements for compressive strength called for in the ASTM designations.

Thin panels offer two advantages: savings in the cost of the stone and savings in weight resulting in the use of less structural steel to support the stone. Because of the increased cost of structural steel, there is constant pressure to reduce the weight and hence the thickness of panels. When carried to excess, this can result in failure of the panels. The problem is especially acute when very large panels are used.

Slate generally is used in natural thicknesses, commonly ranging from 6 to 50 mm and with natural cleft or face showing. Honing the surface destroys the natural beauty of the stone and increases the chance of deleterious weathering. Slabs too thick for a particu-

lar application can be ground to specification on the reverse side. Most slate is used for roofing and flooring. Other uses are for billiard tables, electric panels, blackboards, mantels, window sills, and similar functions.

Natural stone used in conjunction with other structural materials is a significant development in the dimension stone industry. This approach developed naturally with the use of very thin slabs in the marble industry; now limestone, granite, and slate are being individually suspended on the face of buildings so as to allow movement at the interface. Elastic jointing compounds have made weathertight seals possible. Stone is commonly preassembled into units such as column covers and window frames using epoxy glue and metal supports. The units are furnished with brackets for easy attachment to hangers built into structural members of the building.

A trend in the application of all kinds of dimension stone is toward larger slabs. It is not uncommon for limestone and granite panels to be used in single floor-to-floor spans. Marble slabs are more limited in size (2 m²), but marble-faced panels backed with precast concrete can be produced in single units for floor-to-floor installation. Because many of the large slabs are supported at top and bottom only, producers and producer associations have adopted wind load and other design specifications relating the size of the panel to the thickness of the stone in order to give adequate strength. Furthermore, these requirements have put additional burdens on the quarrier because no physical flaws in the stone along which separation might occur can be tolerated. Whereas smaller-sized pieces could be cut between natural flaws in a block, the quarrier is now called on to produce large, virtually flaw-free blocks of stone.

Although color and pattern are inherent qualities of stone, they can be influenced by the finish. Polished finishes tend to darken color and show vivid contrasts. Rough-textured surfaces tend to lighten color and subdue patterns but tend to catch dirt. Polished marble is used extensively on interior walls where the natural color and veining of many exotic marbles are used to advantage. In exterior work where uniform color and subdued pattern are currently in favor, rough-textured finishes can be used except where airborne

Figure 2. A polished green serpentine marble slab in Amman, Jordan

soot is a problem. These surfaces are achieved by abrading the surface or, in the case of granite, flame treating.

Granite and serpentine marble, or verde antique (Figure 2), are favored stone for use in the base course and entrance features of large buildings. These are the only natural stones that will hold a polish in exterior use, and polished surfaces are easily maintained as well as attractive.

Although seldom actually specified, the long-term availability of a particular stone may be an important factor in its selection for some uses. This is because of the possibility of additions or repair work that must match the original structure. A related factor is that some architects may prefer established building stones with which they are familiar. These considerations give long-established quarries an advantage over new or untried stone despite any other considerations.

Tile

Tile is thin (1 cm) stone cut into square or rectangular shapes, almost always with a polished surface. In the United States, tile is still sold in 1-sq-ft pieces or sizes that are integrally divisible into 1 ft. The principal use is flooring, but it can also be used on walls and countertops. Consumption of tile in the United States has greatly expanded in recent years, mostly because of the advent of automated tile cutting and polishing machines. Most stone tile currently produced is marble because of the ease of cutting and polishing, but granite tile is increasingly produced and consumed. Blocks not suitable for making large panels can be used for tile, an advantage to the producer.

Monumental Stone

Monumental stone encompasses a variety of products ranging from simple grave markers to statues, mausoleums, and elaborate structures such as the Lincoln and Jefferson memorials in Washington,

D.C. In construction and fabrication, the larger memorials and mausoleums differ little from building construction except that they may contain more elaborate carving.

Granite and marble, particularly white marble, are the preferred stones for monumental use. According to USGS statistics, more than half the granite quarried is used for monumental purposes. Georgia and Vermont are the largest producers of monumental marble, but the producing companies provide more building than monumental stone.

Standard sizes for building stones do not apply to monumental stone unless the purchaser specifies. The principal requirements are for uniformity of texture and color, freedom from flaws, suitability for polishing and carving, and resistance to weathering. These qualities either are aesthetic, and hence not amenable to standard specifications, or are qualities best determined by experience. So far, no one has developed a satisfactory test to predetermine the resistance of a stone to weathering.

Ashlar

Ashlar consists of rectangular pieces of stone of nonuniform size that are set randomly in a wall. The exposed surface of each piece is generally less than 0.4 m^2 , and the surface can be squared (smooth face) or roughewn (rock face). Ashlar blocks are prepared to specified thicknesses, usually about 75 mm. Ashlar can be squared from quarry blocks that are not suitable for finishing to cut dimension stone or it can be made from rocks that break naturally into rectangular pieces. Although smooth-face ashlar was popular in the past, the roughewn look of rock face is more in demand today.

Split-faced Ashlar

Split-faced ashlar consists of brick-shaped blocks of stone that are laid in courses. Blocks of marble or limestone are sawed into modular thicknesses and then split with a power-driven wedge called a guillotine. The blocks are trimmed and laid in courses with the broken face showing. Natural flagstones (sandstone, slate, and limestone) are similarly broken into brick-shaped pieces, differing only in that the thickness is not precisely controlled. In the limestone and marble industry, split-faced ashlar consumes much stone that is considered waste in the production of dimension stone.

Roofing Slate

During the last decade, the volume of slate being used has substantially increased. Domestic U.S. sources are being augmented by imports from Canada, Brazil, Spain, India, and China. Used both in new construction as well as for repairs and restoration of older buildings, slate is considered by many to be the most permanent type of roof covering. Standard specifications for roofing slate are given in ASTM C406.

Mill Stock Slate

Smooth-finished slabs of slate are used for electric switchboard panels, billiard tables, blackboards, counter tops, and similar purposes. Electric slate must have high electrical resistance and be free of magnetite and other conducting minerals.

Slate Dimension Stone

Either cleaved or smooth-finished slate can be used as hearthstones, mantels, steps, sills, or other structural purposes. Standard specifications for structural slate are given in ASTM C629.

Curbing

Granite curbing is used in large quantities because of its superior resistance to abrasion and weathering. In areas of abundant

freeze–thaw cycling where deicing salts are used, granite has proved an especially resistant material. Granite curbing is broken out along the rift and grain of the stone, but it is also possible to break out curved pieces by close drilling. Mt. Airy Granite Co. of North Carolina specifies a sawed upper surface, but the face and back are smooth-quarry split.

Miscellaneous Uses

Other uses of dimension stone include laboratory furniture and sinks, for which soapstone is considered the premium material. Sandstone, quartzite, and granite are used to line tube mills for grinding ore or other material. Precision surface plates for mounting optical instruments and fine machine work are made from granite, while sandstone and soapstone have been used as refractory brick. In the past, large numbers of grindstones and millstones were made from sandstone or granite. Arkansas novaculite, a fine-grained quartzite, is fashioned into hones. Because of its resistance to chemical corrosion and its favorable physical properties, granite is used to make cylinders up to 9.1 m long and 1.5 m or more in diameter for grinding pulp in paper mills. It is also used as skid caps and tank liners in steel pickling mills (Richter 1988).

LITHOLOGIC CLASSIFICATION

Almost every variety of rock can or has been used as dimension stone. The suitability of a particular stone is governed primarily by physical properties and aesthetic appeal. Mineralogy and chemistry are, for the most part, important only indirectly as they bear on the physical properties. The exception to this statement is the resistance of a rock to weathering, which is profoundly affected by mineralogy and chemistry as well as by physical properties.

ASTM has adopted standard definitions for granite, limestone, marble, greenstone, sandstone, slate, and certain subdivisions and varieties of each (ASTM C119). Standard geologic nomenclature and classification of rocks is needlessly cumbersome for an industry that is dominated by sales-oriented people and architects. Commercial definitions, however, recognize and respect history and use within the industry while attempting to keep the commercial definitions compatible with scientific terminology. This sometimes creates confusion. The following sections discuss both scientific and commercial definitions.

Granite

Commercial Definition

Commercial granite includes all feldspathic rocks of visibly granular or gneissic texture, including granite family rocks as defined scientifically, plus syenite, gabbro, anorthosite, and other plutonic igneous rocks. In commercial usage, fine-grained igneous rocks such as diabase or basalt are sometimes called black granite. Commercial granites are commonly named for the quarry or location where they are found, with names modified by adjectives giving color, texture, or some exotic description.

Scientific Definition

To the petrologist, granite is a visibly crystalline rock with interlocking texture and composed essentially of alkali feldspar and quartz. A member of the granite family of rocks that includes all rocks with granitic texture, it is composed of essential quartz and feldspar. The granite family is subdivided into specific members, such as granite (proper) and granodiorite, on the basis of the kind and proportion of the three major feldspar varieties in the rock. All members of the family contain quartz, and most contain minor accessory minerals such as biotite, muscovite, hornblende, and pyroxene.

Granitoid rocks containing essential feldspar, but without quartz, are called syenite if alkali feldspar predominates; diorite if calcium feldspar predominates; or monzonite if the feldspar are about equal in abundance. These rocks typically contain considerable amounts of ferro-magnesian minerals such as biotite, hornblende, and pyroxene as accessories. Rocks with approximately equal proportions of calcium feldspar and pyroxene are classed as gabbro or norite and are included in the typical black granites of commercial usage. Rocks with mineral composition of the granite family, but with a texture that shows distinct planar or linear properties owing to the parallel alignment of mineral grains, are called gneiss.

Most of the rocks discussed in this section are classed as plutonic by geologists, meaning that they formed deep within the earth's crust and characteristically have a visibly granular texture. Exceptions are basalt family rocks, generally known as traprock and sold as black granite. All but gneiss are typically of igneous origin, meaning that they formed by consolidation from molten material (magma). Most gneisses and some granite family members, however, are thought to have been formed by metamorphism; that is, by transformation from preexisting sedimentary or other rocks.

Granite family rocks can occur as dikes, sills, or large subadjacent masses of irregular or globular shape. For practical economic purposes, they can be considered bottomless. The mode of emplacement can be by forceful injection where the magma shoulders aside the country rock, or it can be more passive, in the form of stoping where the rising magma engulfs fragments of the country rock (which either sink into or are resorbed by the magma). Most granites are thought to have been emplaced in the roots of mountains that form at convergent plate margins and are exposed only after profound erosion has removed the covering rocks. Granite emplacement can be contemporaneous with orogenic folding (synorogenic) or can follow the principal orogenic movements (postorogenic). Postorogenic granites, passively emplaced by block stoping, are more apt to be free of internal strain and usually make better dimension stone.

Sandstone

Commercial Definition

ASTM defines commercial sandstone as “sedimentary rock composed mostly of mineral and rock fragments within the sand size range (2–0.06 mm) and having a minimum of 60% free silica, cemented or bonded to a greater or lesser degree by various materials including silica, iron oxides, carbonates, or clay, and which fractures around (not through) the constituent grains” (ASTM C119). This definition unnecessarily excludes many arkoses that have less than 60% free silica, including some brownstones from the Connecticut Valley (see Pettijohn 1975).

ASTM defines quartzitic sandstone as having 90% free silica and quartzite as “highly indurated, typically metamorphosed sandstone containing at least 95% free silica, which fractures conchoidally through the grains” (ASTM C119). This definition would exclude many metamorphosed sandstones mapped as quartzites by geologists.

Common commercial varieties of sandstone quarried in the United States include bluestone, “a dense, hard, fine-grained, commonly feldspathic sandstone of medium to dark greenish-gray or bluish-gray color that may split readily along original bedding planes to form thin slabs;” and brownstone, “a dense medium-grained stone, locally grading to conglomerate, with a distinctive dark brown to red color” (ASTM C119). Typical brownstones are

arkosic sandstones quarried from Triassic basins in the eastern United States. Freestone is sandstone or limestone that splits with equal ease in any direction.

Scientific Definition

Sandstone is a clastic sedimentary rock composed of indurated sand grains, most of which fall within the size range $\frac{1}{16}$ in. to 2 mm. The interstices typically contain cementing material, but enough voids can remain to give the rock considerable porosity and permeability. Rocks composed of clastic fragments larger than sand-size are called conglomerate if the pieces are rounded, or breccia if angular. Rocks composed of clastic particles smaller than sand-size are siltstone or shale.

Sandstones are deposited by waning currents, mostly in water, rarely by wind. They are the end product of a weathering and erosion cycle that starts with the disintegration and decomposition of source rock, followed by erosion and transportation of the resulting material to a final resting place where the sediment is deposited in horizontal layers. Quartz is the only abundant sand-size material in the source rocks that strongly resists alteration or decomposition by weathering. Typically, feldspar and other labile materials are depleted during the cycle, leaving a concentrated residue of quartz. The amount of quartz concentration is a measure of the maturity of the sand. Quartz-rich sandstones, sometimes called orthoquartzites, tend to be well sorted and cemented with secondarily precipitated calcite or silica.

Immature sandstones containing abundant feldspar are called feldspathic sandstones (5% to 25% feldspar) or arkoses (more than 25% feldspar). Alternately, immature sandstone containing abundant rock fragments is referred to as lithic sandstone, subgraywacke, or graywacke. Immature sandstones tend to be poorly sorted with the interstices commonly filled with clay, iron oxide, and other detritus.

Perhaps the most conspicuous feature of sandstone is bedding or stratification, which was formed by successive influxes of sediment. Bedding planes commonly are parting planes, and the direction of bedding is called *rift* in the industry. Those bedding planes, along which the rock splits with greatest ease, are termed *reefs*. Some sandstones have a second direction of easy splitting that is nearly perpendicular to bedding. The second direction, called *run*, can be of great aid to the quarrier.

Sandstones with thin, even, and regular bedding along which the rock easily splits are natural flagstones. Sandstones that are sawed into cut dimension stone must have massive beds, as the saw cuts are generally made perpendicular to the bedding. Some sandstone layers have internal cross-bedding that is not parallel to the principal stratification. If the stone parts along the cross-bedding, it is unsuitable for dimension stone.

Limestone

Commercial Definition

Limestone is "a rock of sedimentary origin composed principally of calcium carbonate . . . or the double carbonate of calcium and magnesium . . . or some combination of these" (ASTM C119). In its most recent designation, ASTM (C 119) recognizes the following special varieties: calcarenite, coquina, dolomite, microcrystalline limestone, oolitic limestone, and recrystallized limestone. Of these terms, only calcarenite, coquina, and oolitic limestone are commonly used in commerce.

Limestones are commonly designated by location and texture (e.g., Indiana Oolitic Limestone). The color may be included in a name such as Cream Kasota Vein, or other descriptive or exotic terminology may be used as sales representation dictates.

The Building Stone Institute, following industry usage, has defined an oolitic limestone as a stone formed of shells and shell fragments that are of more or less uniform size and generally 2 mm or less in greatest dimension. The original fossil texture is well preserved. By the present ASTM definition, such a rock should be called calcarenite. Because many commercial oolitic limestones are composed in whole or part of oolites, which are tiny spheres of calcite or aragonite, they would also fit the scientific definition of calcarenite.

Shell limestones generally contain larger unbroken fossil shells enclosed in a fine-grained matrix. Coquinas are composed of loosely cemented shells and shell fragments.

Travertine and recrystallized limestone can be considered either limestone or marble, based on the ability to take a polish.

Scientific Definition

Limestone is a sedimentary rock composed of one or both of the two polymorphs of calcium carbonate—calcite and aragonite. Although aragonite is common in limestones of Recent age, because it is unstable and inverts to calcite, it is rare or absent in ancient limestones. Sedimentary rock composed of the mineral dolomite (calcium-magnesium carbonate) is called dolomite or dolostone. Dolomitic limestone contains calcite and dolomite; magnesian limestone contains magnesium carbonate but not necessarily as dolomite. Many limestones and dolostones contain abundant sand or clay, in which case they may be called sandy or argillaceous limestone (or dolostone).

The vast majority of limestones are composed of shells or shell fragments. When deposited in turbulent water, the fragments are broken, sorted, and reworked. Resulting features such as size sorting and bedding are the same as for sandstones, and the rocks have been called calcarenites, where the word "arenite" designates sand-sized particles. In quiet water, the sturdier shells can remain intact but other shells readily disintegrate into ultrafine particles that can wash out, leaving a residue of larger shells sorted as to size. In very quiet water, the ultrafine material plus the shells of one-celled microorganisms can form a matrix in which larger fossils may or may not be embedded. Rocks composed of finely commuted calcite are called calcilutites. Limestones composed predominantly or entirely of the shells of microorganisms are called chalk.

The only limestones known to form by direct chemical precipitation in open seas are in the form of oolites. Oolites are commonly formed with a concentric structure around a nucleus consisting of a tiny fossil or other fragment. Modern studies show that oolites form in shallow, turbulent, warm seas where loss of carbon dioxide to the atmosphere causes supersaturation of calcium carbonate. Oolitic limestones can be composed entirely of oolites or of a mixture of oolites and shell fragments.

Modern petrologic studies show that much of the finely commuted material in limestones is reworked by burrowing organisms and pelletized by filter feeders. Modern carbonate classifications are based on the texture of particles—be they fossil fragments, pellets, oolites, or other fragments—and the degree of sorting of the particles. For further information, the reader is referred to various texts on sedimentary petrology and the chapter on Limestone and Dolomite in this book.

The origin of dolostone is less clear. Some appear to form by in situ replacement of calcium by magnesium, and the resulting stone commonly retains the texture and structure of the original limestone. Other dolomites are thought to form by direct precipitation in hypersaline waters where the climate is hot and dry.

Marble

Commercial Definition

Commercial marble is any crystalline rock composed predominantly of calcite, dolomite, or serpentine that is capable of taking a polish (ASTM C119). Marble is probably the oldest term used for dimension stone. In ancient Rome, the root word for marble—*mar-mare*—was used for all hard stones that could be polished. The same practice is followed in Italy today where the term “marble” is used for all hard stone that will take a polish, including granite. The practice is not followed in the United States, where commercial marble encompasses true marble in the geologic sense as well as many crystalline limestones, travertines, and serpentine, but not other lithologies.

Travertine is a cellular limestone deposited from hot springs. Onyx marble is a dense, crystalline form of limestone, deposited from cold water solutions and commonly found in caves. Verde antique is massive serpentine, commonly crisscrossed by veinlets of calcite and capable of taking a high polish.

Commercial trade names commonly give the quarry location, color, and an adjective describing the pattern or texture of the stone. Where a pattern is referred to as veined, the stone is generally cut across the bedding or layering. Fleuri patterns are achieved by cutting parallel to layering.

Scientific Definition

Marble in geology usage is a metamorphosed limestone or dolostone that is so thoroughly recrystallized that much or all of the sedimentary and biologic textures are obliterated. The result is an interlocking, mosaic texture. Bedding can be partially preserved in the form of compositional layering or banding. Where deformation is intense, the layering can be folded, stretched, and pulled apart, producing a swirly marbleized appearance (which, in an interesting note, gives “marble cake” its name).

Impurities present in the original carbonate sediment form a characteristic suite of magnesium and lime silicate accessory minerals. Most limestones are slightly magnesian to dolomitic, and the chief mineral impurities are quartz and clay minerals. Common accessory minerals are talc, chlorite, amphibole, and pyroxene. Accessory minerals are colorless to golden-brown magnesian varieties if iron is absent, but green if iron is present. Organic material entrapped within the rock forms graphite that is commonly accompanied by finely disseminated pyrite. Pure calcite marble is white, but tiny amounts of impurities will color it significantly. Graphite and pyrite commonly color marble gray. Finely disseminated hematite will color marble pink.

Most true marbles are deformed rocks in which original bedding planes have been folded, crumpled, or otherwise distorted. The crumpling is generally most intense along the axes of folds. On the limbs, the layering may remain straight and planar. Such is the case in West Rutland, Vermont, where the character of the marble is consistent parallel to the layering, but changes markedly across the layering. On the limbs of folds, the layers may be stretched rather than crumpled. In some Alabama deposits, brittle interbeds of dolomite marble have broken and pulled apart during deformation, and more plastic calcite marble squeezed into the spaces around the broken pieces. At Tate, Georgia, a combination of intense crumpling and stretching has practically obliterated all sense of the original bedding and the entire deposit is a nearly homogeneous mass of swirly veined marble.

Crystalline limestones that take a polish are commercially classified as marble. Such limestones are not considered marble by petrologists, particularly if sedimentary and biologic textures are

well preserved. These dense, nonporous rocks may show recrystallization of the matrix and be thoroughly cemented with secondary calcite. Many of the more decorative marbles are of this class.

Serpentine, classified as marble commercially, is not so delineated by petrologists. Most serpentine results from metamorphism of peridotite and related rock. Originally composed of pyroxene and olivine, peridotites are recrystallized at relatively low metamorphic temperatures in the presence of water to form serpentine minerals (hydrated magnesian silicates) and amphibole. Iron released in the reaction commonly forms magnetite, and lime released from pyroxene, or introduced from outside, commonly forms calcite veinlets. Serpentine commonly forms in tabular or lens-shaped bodies associated with other metamorphic rocks.

Travertine is a dense, commonly banded and cellular limestone deposited by chemical precipitation from springs or rivers. It is a hard, dense form of tufa. Much of the cellular structure is thought to have formed from the weathering out of plants or other debris around which the travertine precipitated.

Slate

For both commercial and scientific purposes, commercial slate is defined as a microgranular metamorphic rock derived from argillaceous sediments. It is characterized by closely spaced parting planes called rock cleavage, which is entirely independent of original bedding. The cleavage permits the rock to split easily into thin slabs (ASTM C119). Slates are formed by dynamic metamorphism. Beds of differing composition that form color stripes on cleaved surfaces are called ribbons, which are considered deleterious in high-grade slate. The best slate, therefore, comes from rocks having thick, massive, original bedding.

Quartz is usually the dominant mineral, but extremely fine-grained mica and other platy minerals are always present. The platy minerals tend to be aligned with the slaty cleavage and impart a sheen to the surface. Most slates contain pyrite or iron oxide and many contain graphite. The color of slate is determined principally by the oxidation state of the iron and the amount of graphite or other coloring material present. Graphite and pyrite impart a dark gray or black color; ferric iron oxides color the slate red. Green slates owe their color to the presence of chlorite, other iron silicates, or ferrous iron oxides.

Other Stone

Other rock types sold as dimension stone include greenstone, soapstone, and traprock or basalt.

Greenstone

Greenstone is a metamorphic rock containing “one or more of the following minerals: chlorite, epidote, or actinolite” (ASTM C119). It is derived by metamorphism of basalt, diabase, or other mafic igneous rocks.

Soapstone

Soapstone is a metamorphic rock derived from peridotite or other ultrabasic rocks and composed principally of talc. It has great heat-retaining properties and chemical inertness. For this reason, it is used for laboratory furniture, stoves, and fireplaces.

Basalt

Basalt is a microcrystalline volcanic rock composed of pyroxene and calcic plagioclase. Traprock is a common term for dike rock of the same composition. The correct petrologic term for traprock is diabase or dolerite. Diabase can have columnar jointing but lacks

flow structures and commonly is coarser grained than basalt. When sold for dimension stone, it is commonly called black granite or traprock.

QUARRY METHODS

Quarry operations typically involve isolating a mass of stone by cutting it free from the parent mass on all sides but one (Figure 3). The isolated mass is then lifted or separated from the parent mass by breaking it free or by undercutting it with a wire or chain saw. The freed stone can be a block size suitable for sale or further processing—a mill block—or it can be much larger—a quarry block (Figure 4). Quarry blocks are subdivided by breaking into smaller blocks that can be removed from the quarry and sent to the mill. Typical mill blocks range in size from 12 t to 30 t, but they can reach weights as large as 65 t. Quarry operations thus involve cutting the stone, breaking the stone, and removing the stone from the quarry.

Quarry Plan

The quarry plan is determined by the geometry of the deposit, the amount of overburden, and the necessity of handling rectangular blocks weighing up to 65 t. Most quarries are the open-pit type (Figure 5). They have relatively small surface area and are worked downward in a pit below the general surface level. Open-pit quarries have several advantageous characteristics:

- They can be located on outcrops or where overburden is thin.
- They are within reach of fixed derricks with movable booms.
- Electric service, air compressors, loading docks, and other service facilities can be more or less permanently fixed near the working area.

Traditionally, the quarry size is limited by the reach of the derrick boom. Larger open-pit quarries generally require several derricks, both for lifting out blocks and for emplacing and moving quarry machinery. In recent years, many operators have used large tractors, forklifts, and other machinery to move equipment and quarry blocks across the quarry floor, thus extending the reach of the derrick boom. Some have eliminated derricks altogether and built ramps to give access to fork lifts and other mobile equipment for moving blocks and equipment.

Open-pit quarries are particularly well suited to massive deposits such as granite and some marble formations (Figure 6). Steeply dipping layered deposits are also quarried by this method, and the hanging wall is commonly undercut. Wall support is generally not required where a single derrick makes one opening. If successive quarries are opened along the strike, however, a web between quarries can be left for wall support.

The depth of open-pit quarries is limited by the thickness or depth of good stone, by spalling or so-called pressure breaks, or by excessive time loss in entering and leaving the quarry and in lifting out blocks. Open pits seldom reach depths of more than 75 m.

Flat-lying, layered deposits can be worked as open-shelf quarries in a hillside. In this case, the quarry floor is level with the ground on one side. If the deposit is thick, the quarry can be changed into an open pit as deeper layers are removed. The quarry can also be extended under the hill as an underground quarry if the overburden is too thick for removal on the high side (Figure 7).

Blocks are nearly always cut parallel to layering if the layering is pronounced and regular. Therefore, where layering is tilted, the quarry floors are not flat. This increases the difficulty of moving equipment and removing blocks. Movable equipment, such as tractors and forklifts, cannot be used, and enough derricks must be set to reach the entire working area of the quarry.

Underground quarries are room- and-pillar mines. Generally, no more than 25% and commonly as little as 15% of the stone is left for roof support. Underground derricks are set for loading blocks. These can be of the fixed-boom type, as blocks are generally skidded under them for loading onto trucks or other conveyances. In recent years, forklifts strong enough to lift quarry blocks have become available, eliminating the need for underground derricks in flat-floored quarries.

The initial opening of a tunnel quarry can be made by cutting out blocks in a manner similar to removing key blocks in an open quarry. The cost of removing these key or tunnel blocks is higher than for removing floor blocks. After the initial opening is made, quarry methods are generally the same as for open quarries except for block removal. Alternatively, some underground marble quarries in Vermont have been opened by removing an overlying layer of rock with conventional mining methods (i.e., blasting and mucking). More efficient quarry equipment has made underground mining unnecessary.

Cutting the Stone

Channeling Machines

One of the oldest methods for cutting stone is with channeling machines that cut with the chopping action of several chisel-edged steel bars clamped together. The machine travels back and forth on tracks, cutting a channel 50 to 64 mm wide. As the channel is deepened, longer bars are substituted in the machine. Because the method is slow and the channel bars require frequent sharpening, the quarry is practically obliged to have a blacksmith shop. Channeling has generally been replaced by other quarry methods.

Drilling and Broaching

Drilling and broaching is another long-established method for cutting stone. Drill and broaching tools are mounted on a quarry bar built into a rigid frame. The tools slide along the bar, which serves to align a series of closely spaced holes. The web between these is cut out by the chiseling and chopping action of the broaching tool. Although the method is suitable for all kinds of stone, drilling and broaching is slow, and, like channeling steel, the broaching steel requires frequent sharpening. In modern quarries, the method has largely been replaced by line drilling.

Courtesy of Geomapping/Technographics.

Figure 7. New tunnel opening in a Vermont marble quarry

Line Drilling

In line drilling, also called slot drilling, a line of overlapping holes is drilled. The drill is mounted on a quarry bar or frame, which serves to align the holes and hold the drill rigidly in position. A key to successful line drilling is a guide attached to the drill that is inserted into the last complete hole in the line and serves to ensure that successive holes overlap. The Tamrock Company has developed a machine (Slot Drill 600) that mechanically spaces 64-mm holes, then drills the web between them using a special guide. Tamrock claims a maximum depth of 6 m for the system. This machine illustrates a trend toward mechanization that cuts labor costs.

Jet Channeling

Jet channeling is the most common method of cutting granite. Also known as flame-cutting, this method consists of disintegrating the rock with intense heat from the combustion of fuel oil and oxygen. The thermal shock causes the rock to spall, and the fragments are blown from the channel. The torch, which is passed back and forth over the rock, is commonly attached to a frame in order to keep the cut true. In some granite quarries, large blocks are freed using this method and then are subdivided by using cheaper methods of breaking the rock. Although jet channeling works well in granite and other quartz-bearing igneous rocks that spall, it does not work in quartz-free rocks or carbonate rocks that calcine or fuse rather than spall.

Jet channeling has two significant disadvantages: (1) the noise level is high enough to constitute a serious health hazard, and (2) the kerf is wide and irregular, thus wasting stone. For these reasons, jet channeling is being replaced by other methods.

Figure 8. Wire and chain saw in Vermont

Wire Saws Using Abrasives

Wire saws using quartz sand or silicon carbide have been used for many years to cut marble and, more rarely, granite and limestone. The method, once dominant in some marble districts, has been and is being replaced by diamond wire saws (see following section).

The wire saw consists of a single, double, or triple strand of wire that runs over sheaves and is fed under tension into the stone. Sand, aluminum oxide, silicon carbide, or another abrasive is fed to the wire and wears a groove or channel in the stone. The sheaves are mounted on a tower or track so that they can be moved into the cut. In order to press the wire into the cut, there must be two free and parallel sides to the block of stone being cut, or else a large hole to admit the sheaves must be drilled. In some cases, the hole need only be large enough to admit the axle, hub, and supporting arm of the sheave. As it is pressed into the stone, the sheave is designed to cut its own groove. In some operations, other methods are used to cut parallel channels between which the stone can be wire-sawed.

The wire itself abrades and must last for the entire cut. If it breaks before the cut is finished, the kerf may be too small to insert a new wire and the cut is lost. Therefore, the wire is commonly several thousand meters long.

A single wire can be used to make many parallel or other cuts by guiding it with appropriate sheaves. In order to keep tension on the wire, at least one movable sheave must be set up with appropriate counterweights. Wire-sawing produces a smooth cut that minimizes subsequent finishing in the shop and saves stone in the mill.

Diamond Wire Saws

During the 1970s, diamond wire saws were introduced into the stone industry, first in mills and shops, then into the quarries. Since then, they have continued to replace the older wire-saw techniques. Detailed descriptions of the diamond wire are given in Hawkins et al. (1990) and Cia and Mancini (1989). The wire is a steel cable on which small, diamond-impregnated or diamond-bonded, cylindrical beads are mounted. The beads are separated by either wire springs for soft, nonabrasive rock or plastic for hard, abrasive rock. The wire is looped through drill holes and run by a motor-driven drive wheel mounted on tracks. Tension is provided by pulling the drive wheel assembly away from the cut on the tracks. Cuts can be either vertical or horizontal.

Because most cuts require the drilling of two intersecting holes, the wire must make a sharp angle when the cut is started, which becomes rounded as cutting proceeds. This requires care in providing correct tension during various phases of the cut. Cooling and lubrication is provided by water.

The technique requires precise drilling of the intersecting holes. In order to loop the wire, a nylon line is attached to a ball or wad of paper or other material that is forced through the holes hydraulically or with compressed air. The diamond wire can then be pulled through the intersecting holes with the nylon line. Further details can be provided by the Diamond Bort Company of Columbia, South Carolina.

Chain and Belt Saws

Chain saws using carbide teeth were used more than 30 years ago to cut soapstone in Virginia. More sophisticated saws made in Europe and also using carbide teeth were used to cut limestone and soft marble but were unsuccessful for cutting harder stone. Finally, with the incorporation of diamond-set teeth, chain saws became practical for use in marble and slate. The most recent development is a belt saw in which a neoprene belt carrying diamonds embedded in metal segments replaces the chain (Figure 8). Cooling and lubricating water flows through the blade, which is hollow. Blades up to 5 m long are used in softer limestone; shorter blades are used in harder stone such as marble. Belt saws are also used in sandstone and slate but apparently not yet in granite. Ultimately, belt or chain saws will probably be used successfully in granite and other hard stone.

Water Jet

A promising new development in cutting granite is the water jet. A pulsating jet of water at pressures ranging from 96.5 to 275.8 MPa is directed at the granite and causes it to disintegrate. It is less noisy, produces less dust, and promises to be more economical than jet piercing. Rocky Mountain Rose Re d, Inc., of Lyons, Colorado, is currently using a water jet system (Anon. 1991; Zielinski 1992). The Elberton Granite Association in Georgia has tested two experimental machines, but they have apparently been less successful than diamond wire saws.

Breaking and Lifting the Stone

In open-pit quarries, vertical cuts are made by dividing the floor of the quarry into appropriately sized blocks. After an initial key block is broken free by drilling a hole in the center to the depth of the vertical cuts, an explosive charge in this hole frees the block with or without damage to the block. Alternatively, the block can be wedged free or forced free with an air bladder. In underground quarries, essentially the same technique is used except the initial cuts are horizontal and the key block is taken out of the tunnel face.

Once the key block is removed, a series of closely spaced holes is drilled underneath or behind the remaining blocks, and they are broken free with the use of feathers and wedges, with explosives, or, in some cases, wire saws. Feathers are pieces of half-round steel that are inserted into the hole. To produce the break, steel wedges are driven between the feathers.

Dimension stone quarriers have traditionally shied away from use of explosives, but recent experience indicates that, if used properly, explosives can be successfully and economically employed without damaging the stone. Most modern quarriers use explosives to break the block free. Primacord or light plastic-enclosed charges inserted into the holes generally provide enough force and do not damage the stone. When a block of stone is broken free, it can be further subdivided by the same technique.

Courtesy of Geomapping/Technographics.

Figure 9. Prospect opening in granite with heavy equipment in Vermont

Granite typically has two directions of easy breakage, called rift and grain, or rift and run. In some quarries, large blocks containing many thousand cubic meters of stone are cut free by jet channeling or other means. These blocks are then broken into mill-size blocks along the rift and run directions. Some granite ledge quarries rely entirely on breakage to produce dimension blocks. Holes drilled for feathers and wedges in granite commonly need penetrate only a few centimeters of stone. If the rift is strong, the break produced runs true for the entire length of the block. If the rift is not strong, however, drill holes can penetrate the entire width of the block as in the so-called Finnish method (described in the next paragraph). Often, odd-shaped blocks are trimmed and squared by line drilling and breaking.

In the Finnish method, marble and limestone are often cut into pieces of appropriate height and width for mill blocks, but of much greater length than granite. These are then lifted (broken free from the quarry floor), using feathers and wedges. Using the same technique as for granite, the y are also broken into appropriate lengths. Drill holes for the feathers and wedges generally penetrate the entire width of the block.

The stone can also be broken free with air pressure. After a quarry block is cut free on all sides but the bottom, the bottom is drilled as though for using feathers and wedges. A large reinforced bladder is inserted in the vertical kerf that separates the block from the quarry. Air pressure applied to the bladder breaks the block free and sets it out from the quarry face. Usually 23 kg of pressure or less is sufficient. In some cases, the air bladder can also be used to break loose key blocks.

A serious problem in some quarries is the failure of stone to break along predetermined directions. This may happen in stone that does not have a natural grain or in which the quarry direction does not parallel the natural grain. In some deep marble quarries in Georgia, stone that is cut free on the sides has a tendency to break loose from the floor along arch-shaped fractures rather than parallel to the quarry floor. This not only ruins a mill block but presents a costly cleanup problem in order to keep the quarry floor flat. These breaks, called rainbow breaks by the quarriers, are most common in large, deep quarries and where a long period of time has elapsed between cutting the block free on the sides and lifting it from the quarry floor. Some deep quarries have been abandoned because of rainbow breaks, even though the stone was good otherwise.

Some quarriers use a wire saw to cut quarry blocks with a very large surface area. These slabs are broken free, turned on their sides, and broken into appropriately sized mill blocks. This procedure not only eliminates much expensive cutting but allows the quarrier more flexibility in choosing the size and position of the mill blocks to be cut from the slab. The slab can often be subdivided in such a manner that a minimum number of blocks contain natural flaws, whereas the quarrier has less control with a set floor pattern.

Removing Blocks from the Quarry

Mill blocks are traditionally removed from the quarry with fixed derricks. The procedure is slow, and all other operations under the derrick boom must be halted while blocks are removed. The length of the boom also limits the size of some quarries. Blocks can be skidded from greater distance with tractors and crawler-type derricks, which can also add flexibility. A more efficient method is the use of forklifts that are now available in sizes large enough to handle mill blocks. Because forklifts require a flat or nearly flat floor and access ramps, they are not appropriate for all quarries. For large quarries, however, an investment in ramps is probably justified (Figure 9).

Mill Operations

Most stone is sold as blocks, slabs, or finished product. Mill operations involve cutting blocks into slabs and then cutting the slabs into appropriate sizes and shapes for the final product. Finally, the stone surface is given a final finish.

Sawing Slabs

Primary saw cuts can be made with a gang saw, wire saw, or circular saw.

Gang saws consist of a group of flat steel blades set in a frame that moves with a reciprocating motion. The frame is automatically fed into the block at a rate that depends on the type of stone and the abrasive or cutting edge used. A sand-water mixture may be fed into the saw for cutting soft stone. For harder stone such as granite or quartzite, heavier notched blades have been used, and the cutting medium is steel shot. For faster cutting, the blade can be fed with aluminum oxide or another abrasive. Nearly all modern mills use set teeth of diamond or carbide (mounted in wheels that grind the stone to a reciprocal shape just as a wood-router bit shapes a board).

Although carbide can be used for softer limestones, harder rocks, such as marble and granite, require diamonds, which are set in segments that are brazed to the gang saw blade. Set teeth generally cut faster and smoother than loose abrasives. As many as 40 blades can be set in a single gang saw when thin stock is being cut.

In most gang saws, the blade is horizontal and the frame is pressed downward through the block. The size of the block that can be sawed is thus limited by the size of the frame and blades. A newer development is vertically set gangs through which the block moves horizontally, producing longer slabs.

One of the problems in gang saws is keeping equal tension on the blades. If a blade loosens, it can wander or buckle and jam the saw or ruin the cut. The traditional method of holding a blade in position is with wedges driven through a hole in the blade outside the frame. Considerable skill is required to maintain a large number of blades under equal tension in a single frame. A more modern method involves the use of hydraulic tensioners.

Wire saws are commonly used to make primary cuts in granite blocks. These can be grouped into multiple or ganged wire saws. The wire saws can be either twisted wire using abrasive or diamond wire saws.

Wire saws are also used to make irregular or curved cuts. The saw is set vertically and the stone is fed into it as wood is fed into a band saw. Wire saws have also been used to turn large columns, in which case the saw is usually set horizontal and the stone is slowly turned into it.

A recent development in the granite industry is the use of large-diameter circular saws to make primary cuts. The saw makes repeated passes across the block, cutting 5 to 10 mm at each pass. The resulting cut is remarkably smooth so that increased sawing costs are more than compensated for. The largest circular saw in operation is reported to be 4.2 m in diameter and capable of 1.6 m total depth of cut. Another recent development is the use of the W.F. Meyers' narrow-belt block saw for primary cuts in quarries and mills in the Indiana Limestone District.

Secondary Cuts

Sometimes called bridge saws, secondary cuts are set in a frame that guides the saw and, in most modern versions, are automatically controlled, often by computer.

Shaping, Grinding, and Polishing

A wide variety of methods is used for finishing the stone. Shaping can be done using hand-operated pneumatic tools, wire saws that cut as a band saw cuts wood, or silicon carbide. For softer stones, large milling machines employing carbide teeth can be used to gouge shapes into the stone. In modern mills, diamonds have almost universally replaced other abrasives, and automated machines are common.

Cylindrical shapes are made on a lathe that turns the stone into a carbide or diamond bit or into a wire saw. Boring machines can be set with diamonds or with carbide.

In older mills, flat surfaces can be ground on a large horizontal cast-iron wheel called a rubbing bed. A water-sand mixture is used as abrasive. More modern plants have replaced rubbing beds with automatic surfacing machines using impregnated diamonds. The stone is belt-fed under a series of successively finer horizontal wheels. Some machines fine-grind the edge of the stone as well as the surface. Much polishing is still done by a conventional grinding-polishing machine that moves a spindle over the stone surface. Wheels using successively finer abrasives are set on the spindle.

A significant development in the last several years is the introduction of automated tile-making machines that trim and polish the

Courtesy of Geomapping/Technographics.

Figure 10. Automated tile line in Amman, Jordan

tile at lower cost and with more accuracy than previously possible (Figure 10). These machines are largely responsible for the much greater production and consumption of stone tile.

Another significant development is an automated shaping machine that can duplicate intricate, carved pieces. Traditionally, much finishing was hand work by skilled stone workers. As these skills are being lost, much effort has gone into automation of the finishing process.

DISTRIBUTION OF DEPOSITS AND RESERVES

The ultimate reserves of dimension stone must be considered inexhaustible. There can only be shortages of particular types or colors that can be discovered and produced at a competitive price. Although the distribution of various lithologies is a result of geologic factors, the location of producing quarries is governed by economics. Because dimension stone, particularly marble and granite, is traded internationally in blocks, slabs, and finished products, every continent and nearly every country is a producer or potential producer of dimension stone.

Following is a brief summary of the major producing areas, described by lithologies, first in North America, then in the rest of the world.

The United States and Canada

Currier (1960) divided the United States into five geologic provinces for the purpose of describing the distribution of the major lithologies. All but one extend into Canada.

Atlantic and Gulf Coastal Plain Province

The Atlantic and Gulf Coastal Plain lies east and south of the Appalachian Mountains, extending from New York to Alabama, and south of the Interior Sedimentary Province from Alabama through Texas. It is underlain by poorly consolidated sedimentary rocks of Cretaceous and younger age that lie in nearly horizontal strata. Although little dimension stone is produced in the province, soft coquina that hardens on exposure to air has been used as building stone in Florida since the 17th century, and Cretaceous limestone is quarried near Liberty Hill, Texas.

Appalachian Crystalline Province

This province extends from Alabama to Maine and north through eastern Canada to Newfoundland. Because it is the exposed root

Courtesy of Geomapping/Technographics.

Figure 11. White marble quarry in Alabama

zone of an ancient mountain chain that formed during mid-Paleozoic time, it is sometimes called the “older Appalachians.” Granite, gneiss, marble, serpentine, slate, and other crystalline rocks are produced from this region (Figure 11).

Granite. The principal granite-producing areas in this province are in Georgia and New England. North Carolina is also a significant producer.

Georgia produces more granite than any other state or province in North America. The industry is centered in the town of Elberton in northeast Georgia. Unlike many districts, Elberton is not dominated by one company but rather has many producers. Some producers specialize in quarrying blocks, some in sawing slabs, and some in making finished products. Still other companies are vertically integrated, performing all operations from quarry to finished product. The production in Elberton is principally aimed at the memorial market, but structural stone such as building facing and floor tiles is a growing market. In 2003, more than 45 granite quarries were operating in the batholith within a 25-mile radius of Elberton. Elberton firms also operate quarries or buy stone in several other states or countries.

The prevailing method of cutting stone in Elberton is jet channeling, but some operators are switching to high-speed drilling using Tamrock’s slot drill or to diamond wire saws. Because jet channeling is noisy, wasteful, and less efficient than the other methods, this trend will probably continue. A summary of quarry techniques is given in the Elberton *Graniteer* (Anon. 1990a).

The three New England states of Vermont, New Hampshire, and Massachusetts are the primary sources of granite in the Appalachian Crystalline Province. The largest single granite-producing district in this region is in Barre, Vermont, where the Rock of Ages Co. is the sole producer.

Descriptions of the Barre District are given by Richter (1987) and Ratté and Ogden (1989). Since the mid-19th century, granite has been quarried from a mid-Paleozoic pluton, mostly for monuments but also for building facing panels, surface plates, and paper rollers up to 10 m long and 2 m in diameter. Quarriers use natural rift and grain to remove blocks averaging 5 to 6 m³ (Richter 1987).

North Carolina is also a major producer of granite, principally from the Mt. Airy District. Connecticut, Maine, Pennsylvania, and South Carolina are minor producers.

Sandstone. For more than 100 years, arkosic sandstone has been produced from down-faulted basins of Triassic age, which form a subprovince within the Appalachian Crystalline Province (Currier 1960). Known as brownstone, the stone was formerly used extensively for buildings and residences in New England and the mid-Atlantic states but production is much reduced today.

Marble. True marble (i.e., marble formed by metamorphism of limestone or dolostone) occurs throughout the province, and most states within the province have produced marble at one time or another. Today, however, nearly all production comes from Georgia and Vermont with some minor production from Alabama.

The Polycor Group purchased all of what had been the Georgia Marble Company and now extracts marble from several large dimension-stone quarries in Pickens County, Georgia. The stone is medium- to coarse-grained white or light gray and most commonly veined with darker material. The stone is cut with diamond belt saws and quarry bars; quarry blocks are broken free and subdivided using mild explosives in spaced drill holes; and small blocks are removed with large forklifts. Stone from this large-volume, low-recovery operation is used for monuments and buildings.

The Vermont Quarries Company has leased the Danby Imperial Quarry from what had been the Vermont Marble Company. Recent underground expansion has secured reserves of this source of white marble in the town of Danby, Vermont, where a 10- to 20-m-thick layer of Ordovician marble lies in a broad, shallow syncline. Tunnel cuts are made horizontally with a diamond-toothed chain saw, and the sides are cut with a diamond wire saw. Vertical floor cuts are then made with a diamond chain or belt saw and bottom cuts with a diamond wire saw. Average block size is about 20 t (Ratté and Ogden 1989). A complete block-sawing and slab-manufacturing facility has been incorporated in the portion of the underground workings that had been previously quarried.

The black marble quarry at Isle la Motte, Vermont (which was previously owned and operated by the Vermont Marble Company) has been sold, along with the red marble quarry property in Swanton, Vermont. The new owners, a group of Vermont quarriers, have resurrected the operations under the name of Barney Marble—the historical company in Swanton, Vermont, that produced stone from these quarries and supplied many buildings in Washington D.C. in the late 19th century. Similarly, the Rochester Verde Antique quarry at Rochester, Vermont, was sold by the Vermont Marble Company and is supplying stone to the world market under the company name of Vermont Verde Antique International.

Alabama was once a major producer of white marble from the Sylacauga marble belt, but the principal producers have switched to industrial fillers. A small quarry producing block marble for export southwest of Sylacauga has been a small but consistent producer. Marble also has been produced from the Murphy marble belt in western North Carolina. White marble from the Cockeysville Formation in Maryland was used in the Washington Monument, and white marble from Lee, Massachusetts, helped construct the U.S. Capitol building in the last century. During the 1990s, a Canadian firm ceased block production in Lee and none of these districts have significant production today.

Slate. Vermont and Pennsylvania account for 70% of U.S. production of slate. In Vermont, lower Ordovician- and upper Cambrian-aged slates are quarried into blocks by drilling and blasting, followed by manual splitting. The high angle of dip of the slaty cleavage makes conventional quarry techniques difficult. Blocks are taken to the mill where they are cut by diamond saws and trimmed to size for manual splitting into roofing slates. Floor tile and flagging are gauged by planers to specified thicknesses. Structural slate (mantels, electric panels, and similar products) are finished in the mill using standard cutting, honing, and polishing equipment (Ratté and Ogden 1989).

Pennsylvania slates of upper Ordovician age in the Lehigh-Northampton District have a nearly horizontal axial plane cleavage. The slate is quarried in benches 4-m thick using wire saws with silica sand abrasive to isolate quarry blocks. These are then lifted by drilling and wedging. Quarry blocks are reduced to manageable size (mill blocks) by splitting along “watersplits” and a natural grain, or sculp, which is perpendicular to the slaty cleavage. In the mill, diamond saws, splitters, and various other tools turn blocks into finished products (Berkheiser 1984; Colley 1990).

Slate is also produced in Virginia (Sweet 1990), in New York, and intermittently in Nova Scotia and Newfoundland (Vagt and Bergeron 1990) as well as Quebec.

Soapstone. Soapstone is produced in Nelson County, Virginia. Blocks are cut out by a large German-made chain saw and finished into fireplaces, cook stoves, and other products benefiting from the heat-retaining properties of the stone (Sweet 1990). This district was formerly a major producer of laboratory furniture. The greatly increased demand for soapstone is being supplied by Brazilian producers from quarries in the Minas Gerais District of Brazil.

Interior Sedimentary Province

This province extends from the Appalachian Mountains to the Rockies and from Mexico north into the prairie provinces of Canada. It is underlain by nearly flat-lying, mostly marine sedimentary rocks ranging in age from Cambrian to Cretaceous. These sedimentary rocks cover an older, Precambrian basement, which is an extension of the Canadian Shield and is exposed in several isolated uplifts. Limestone, sandstone, and marble (crystalline limestone) are produced from the sedimentary rocks, and granite from basement rocks exposed in the isolated uplifts.

Limestone. The amount of dimension limestone produced in Indiana exceeds the amount of all dimension stone produced in any other state. Indiana limestone has probably been the dominant building stone in the United States for more than a century. The industry is centered around the towns of Bloomington and Bedford in south-central Indiana where quarries have been operated since 1827. The district and its history have been described by Patton and Carr (1982).

The stone has been called Bedford Rock, Bedford Oolitic Limestone, Indiana Oolitic Limestone, and Indiana Limestone. Today Indiana Limestone is a generic term for building stone quarried from the Salem Limestone of Mississippian age in the Bedford-Bloomington District (Patton and Carr 1982). The stone is a light gray to bluish-gray, massive, even-grained, granular, porous, and cross-bedded calcarenite (Patton and Carr 1982). The industry markets buff, gray, and variegated, a combination of the two stone colors.

Because of the district's long history, many kinds of quarry methods have been used to extract stone. Today, many quarries in the district combine W.F. Meyers' diamond-belt quarry saws with diamond wire saws.

In northwestern Alabama, similar stone of the same age is quarried in an underground mine. Here, tunnel cuts are made with three quarry bars mounted on a massive frame and aligned so that the top block tapers to the rear, making extraction easier.

Limestone is also produced from the Oneota Formation of Ordovician age in the upper midwestern United States. In central Texas, limestone is produced from lower Paleozoic rocks.

Marble. Some crystalline limestones within the Interior Province take a polish and, therefore, are classed as marble. The most notable is the Holston Formation in east Tennessee from which vast quantities of Tennessee Marble have been produced. The district lies within the Valley and Ridge Province of the Appalachian Mountains where the rocks are steeply folded and faulted. Blocks must be quarried parallel to bedding, and, because of the steep dip, it is difficult to use forklift trucks and belt or chain saws. Most of the best deposits have been worked as far as possible without underground tunneling. Tennessee Marble remains one of the most attractive and durable dimension stones. One quarry near Friendsville remains in operation with a modern finishing facility that satisfies the current market. In addition, the Imperial Black Marble quarry in Grainer County has been a source of black marble in this area of Tennessee.

Sandstone. Most sandstone production in the United States comes from the Interior Province. Because most sandstone is sold in broken and irregular sizes, however, it does not qualify as dimension stone in this chapter. Bluestone from New York and Pennsylvania is sawed and dressed and a small amount of sandstone from Tennessee is cut and polished for furniture.

Granite. The sedimentary rocks of the Interior Province are underlain by crystalline rocks that are an extension of the Canadian Shield. These basement rocks are exposed in localized uplifts in southeastern Missouri, central Texas, the Arbuckle and Wichita mountains of Oklahoma, and the Black Hills in South Dakota. All of these areas have produced or are producing dimension granite.

Lake Superior Crystalline Province

The Canadian Shield includes the Lake Superior crystalline province of Currier (1960) and underlies most of Canada west of the Maritime Provinces and east of the Rocky Mountains. Although it is underlain by Precambrian rocks—mostly granite and gneiss—extensive marble occurs in the Grenville subprovince of southern Ontario and Quebec.

Granite. In the United States, the principal producer from this province is the Cold Spring Granite Company of Cold Spring, Minnesota, which operates a number of quarries in Minnesota and elsewhere, including Texas and Manitoba.

In Canada, granite is produced in Manitoba, Ontario, and Quebec (Anon. 1990b). Quebec is the largest producer with about 25 active quarries (Nantel 1983; Anon. 1990b).

Although there are few active quarries in the other provinces, the potential is very large. Several provinces are working to find and promote dimension stone deposits. Two provinces, Ontario and Saskatchewan, publish catalogs depicting potential sources.

Other Stone. Only small amounts of other dimension stone, including marble and quartzite, are produced from the Canadian Shield.

Western Province

The Western Province includes a wide variety of subprovinces that encompass nearly every conceivable geologic environment. Nearly every type of rock can be found and at one time or another has been quarried. It is the only province in which recent volcanic rocks are

found and is the only region in North America from which travertine is produced.

Travertine. Travertine deposits are typically associated with recent geologic activity such as volcanism and faulting. For this reason, the Western Province is the only province in the United States and Canada from which travertine is produced. Currently, the only production is from Idaho, Montana, and New Mexico, but potential deposits are known to occur in Oregon and possibly other states.

Two travertine deposits in southeast Idaho are operated by Idaho Travertine, Inc., of Idaho Falls, Idaho. Production since 1968 is said to have averaged 2,000 m³ per year (Neumann 1991). The principal deposit, just west of Swann Valley, Idaho, is a boulder deposit, meaning that it consists of large masses or boulders of travertine embedded in a highly fractured matrix. The boulders are excavated by dozers and loaders. A D-9 dozer fitted with a ripping bar on the front end is used to pry loose the boulders. Those that are too large to transport to the mill are trimmed by line drilling at 15- to 20-cm spacing and blasting with primachord. Recovery is said to range from 5% to 10% of volume removed.

The Montana deposit, near Gardiner, north of Yellowstone Park, is also a boulder deposit, and quarrying methods are similar to that of Idaho Travertine. Five- to ten-ton blocks are removed, and slabs, tile, and ashlar are produced at a shop in Livingston.

About 50 discrete deposits of travertine have been identified in New Mexico (Barker 1986). New Mexico Travertine Co. quarries one of these from a deposit approximately 40 km west of Belen, producing five color-varieties of travertine and one limestone (Austin and Barker 1990). The stone is quarried using a concrete saw to remove cap rock and diamond belt and wire saws to cut the travertine. A mill just west of Belen finishes the stone to polished slabs and split-faced ashlar.

Other Stone. Most of the quarries in the Western Province were worked in the early part of the 20th century and were abandoned long ago. No permanent centers of dimension stone production have developed similar to those in Georgia, Indiana, and Vermont. Information on quarry sites and past activity can be obtained from most state or provincial surveys.

Since the early 1990s, the Colorado Yule marble quarry, Gunnison County, Colorado, which supplied white marble for the Lincoln Memorial and the Tomb of the Unknown Soldier, has been quarrying and selling quarry blocks to domestic finishing shops as well as exporting to off-shore fabricators.

Outside the United States and Canada

International trade in dimension stone is in the form of finished stone ready for installation, in dressed slabs, and in rough blocks or slabs. Granite and marble (including travertine) are the principal rock types, with limestone and slate becoming increasingly important in the marketplace.

As the leading importer of rough blocks and the leading exporter of finished material, Italy dominates international trade, and is also a leading manufacturer of stone-working machinery. It is through the establishment of turnkey finishing facilities around the world that the Italian stone industry has become a principal exporter of equipment and technology, as well as a principal importer of raw blocks. The United States continues to be the principal importer of both finished products and unfinished slabs.

Marble

Most of the world's commercial marble formed from carbonate rocks that were deposited in the great Tethyan seaway that stretched from the Iberian Peninsula to the Himalayas. These rocks were

metamorphosed into marble during the Alpine orogenies and have been quarried since classic times.

The Carrara District in northern Italy produces what is probably the world's most famous marble. Travertine has been produced from Tivoli and marble in many patterns and colors has been quarried in the area since Roman times; the classic names for these have become generic in much of the rest of the world.

In Greece, marble has been quarried from at least the sixth century BC. Recently, the Greek marble industry has undergone a significant revival, and Greece, along with Turkey, has become a major source of marble. China, Israel, Spain, and Mexico have dramatically increased their exports of marble and limestone into the U.S. market (Reis 2004).

Granite

Granite is the most abundant rock on earth and is found on all continents and in most countries. Italy, the major exporter to the United States, gets its stone from Scandinavia or by importing blocks from Scandinavia and shipping finished stone. Other countries that export significant granite to the United States are Brazil, Canada, China, and India. Notably missing from the list are the Scandinavian countries of Finland, Sweden, and Norway, which produce large quantities of granite for the European market. Most of the Scandinavian stone is first shipped to Italy for fabrication before entering the European and North American markets.

Limestone

France, Israel, Jordan, Spain, and Turkey have been major suppliers of limestone to the world market for use as exterior building applications. The ease of working the stone and the natural warm colors make it an attractive stone, both in commercial as well as residential applications.

Soapstone

Brazil has dominated the world market as a source of supply for soapstone. Traditionally, soapstone was used as acid-resistant laboratory counter tops, but composite materials have replaced this outlet. Today, soapstone has gained acceptance for use in residential kitchen and bathroom installations.

Slate

Slate from Brazil, China, India, and Spain has been imported in increasing quantities into the North American marketplace. Although North American brokers are the usual suppliers for the commercial markets, wholesale outlets are the sources for the residential market. Large-scale commercial installations of slate that need a consistent material and reliable supply source are generally serviced by domestic producers.

EVALUATION OF DEPOSITS

In order to properly evaluate a potential dimension stone deposit, one must determine the marketability of the stone; its soundness; its size and shape; the overburden; the distance to market; the kinds of transportation available; the availability of labor; the accessibility of power and other utilities; and similar concerns. Most of these determinations are the same for the evaluation of any mineral deposit, but several are unique to dimension stone deposits.

Marketability

The marketability of a stone is governed largely by aesthetic factors not subject to quantitative measurement, including color, pattern, and texture. Unless the deposit is an extension of a proven quarry or an exact duplicate of a popular stone, the judgment about

marketability should be left to an experienced architect or marketing person.

It is important that a reliable sample be obtained. The best sample is a block from which slabs 0.3 m² or larger can be sawed and used to evaluate color and pattern and also for making required physical tests. The more varied the color and pattern, the larger the sample should be. Drill cores are commonly deceptive but can be suitable for fine-grained uniform-textured stone or for extensions of known deposits.

It is the responsibility of the examining geologist or engineer to determine the size, extent, and uniformity of the deposit and to obtain samples that are truly representative. In the case of layered deposits, samples from each separate stratum should be obtained and compared for uniformity.

Purchasers of stone for large buildings generally make their choice on the basis of the history and reputation of the quarry, samples submitted by the quarrier, or, more commonly, both. Swenson (1991) observed that the buyer is often disappointed because the color and texture of the final product does not meet the buyer's expectations. He pointed out that "stone continually changes during the life of the quarry" (Swenson 1991, p. 46) and samples do not always represent what the quarry is currently producing. The fault may lie with an overly optimistic salesperson, lack of sufficient quarry development, or insufficient knowledge of the deposit. Swenson offered a number of suggestions to architects but warned, "Geologic studies are ineffective in determining the long-term resource . . . but may indicate nothing about the short-term design needs of a project" (Swenson 1991, p. 46). This, it seems, indicates a lack of communication or quarriers' understanding of the limits of geological investigations. Few quarriers have geologists on their staff or even hire consulting geologists. Fewer still map their quarries. Some, like Vermont Marble Co., which remained under the same management for years and had competent geological staffs, knew their deposits intimately and could predict quality and grade with great accuracy. Good, detailed geologic mapping, sometimes supplemented with core drilling, should allow a quarrier to predict changes in the nature of the stone.

One of the problems is that few in the quarry business are knowledgeable enough about modern geology to recognize that a consultant must be either well versed in dimension stone problems, or be a specialist in the lithologic type under consideration, or both. A limestone or crystalline limestone requires a carbonate petrologist; granite requires an igneous petrologist—structural geologist. Whether it is cost-effective to hire a specialist is for the quarriers and architects to decide, but even geologic specialists are generally less expensive than lawyers.

Soundness

Soundness, or freedom from flaws, is one of the most critical factors in evaluating a dimension stone deposit and one of the most difficult to determine. Every joint and fracture should be mapped. This should be supplemented by core drilling parallel to the direction in which the stone is to be sawed. If at all possible, the deposit should be drilled in two intersecting directions in order to find all possible weakness directions that may limit the size of blocks and slabs. If mapping shows a pronounced joint direction, the drilling should be perpendicular to it. The drilling must be done with extreme care, and nothing smaller than NX size should be used. If the core breaks on anything but a natural weakness, the drilling will have failed in its purpose of proving sound stone.

Any directions of natural splitting that would aid in quarrying should be determined. Rift, run, and grain can be beneficial, whereas close-spaced open fractures are deleterious. The investiga-

tor should remember that the ultimate objective is to free large blocks that are without internal fractures.

Some rocks that have been subjected to great stress are still strained. In many cases, such stone will develop new fractures and split after blocks are quarried. Some hidden fractures show up only after the block has been sawed, which proves costly because the flaw appears only after a large investment has been made in the stone. This type of fracture is probably less common in horizontally layered sedimentary rocks and in postorogenic granites that have intruded passively than in rocks that have been subjected to tectonic stress.

Other Factors

The investigator should remember that quarrying blocks for cut and sized dimension stone is still a high labor-input industry. He or she should also keep in mind that each salable unit—a mill block—will weigh 9 t or more and will require special handling methods to extract and transport to market. Compared to other industrial minerals and rocks, the total output of a dimension stone quarry is small. Only a large operation would extract more than a few blocks a day, and few, if any, deposits would justify building new roads, railroads, or expensive utility lines just to service a quarry.

Strontium Minerals

Joyce A. Ober

INTRODUCTION

Strontium occurs commonly in nature, averaging 0.034% of all igneous rock, and is the 15th most abundant element in the earth's crust. Only two minerals, however—celestite, or celestine (strontium sulfate, SrSO_4), and strontianite (strontium carbonate, SrCO_3)—contain strontium in sufficient quantities to make recovery practical, and these minerals are found predominantly in sedimentary rocks. Of the two, celestite is more common in economic deposits. It is similar in structure to barite, the barium sulfate mineral. Strontianite is more desirable of the two common minerals because strontium is used most commonly in the carbonate form and contains more strontium, but few deposits have been discovered that are suitable for economic development. Table 1 lists the properties of celestite and strontianite.

In 2003, celestite production was reported in Argentina, Iran, Mexico, Morocco, Pakistan, Spain, and Turkey (Ober 2004). Although large deposits have been identified in these and other countries, detailed descriptions of the deposits and locations are not available.

Nearly all celestite is converted to strontium carbonate, which may be used as-is or converted into other strontium compounds,

including strontium chloride, chromate, nitrate, oxalate, oxide, and peroxide. The largest end use for strontium is in faceplate glass for cathode-ray tubes (CRTs) such as is used in televisions and computer monitors. Probably the oldest use for strontium is in pyrotechnics such as fireworks, signal flares, and tracer ammunition, because strontium compounds burn with a brilliant crimson flame; strontium nitrate and peroxide are the most common strontium compounds used in pyrotechnics. These and other strontium compounds are used in lesser quantities in ceramics and glass, permanent ferrite magnets, paint, and toothpaste for temperature-sensitive teeth.

MAJOR DEPOSITS AND PRODUCTION

Although the average strontium content of sedimentary rocks is less than in igneous rocks, nearly all commercial operations are in sedimentary deposits. These sedimentary deposits (primarily as celestite) formed in lakes and lagoons by replacement of preexisting clastic sediments and frequently occur as beds or lenses associated with gypsum, anhydrite, or halite. This type of deposit occurs in Iran, Mexico, Spain, the United Kingdom, and the United States. Hydrothermal strontium mineral deposits have been found in Russia and the United States. Infiltration deposits that can be predominantly

Table 1. Physical properties of strontium minerals

Property	Celestite	Strontianite
Chemical formula	SrSO_4	SrCO_3
Crystal structure	Dipyramidal orthorhombic, tabular. Sometimes fibrous and granular.	Dipyramidal orthorhombic. Radiating, columnar, fibrous, or granular.
Cleavage	Perfect basal and prismatic	Imperfect prismatic
Color	Primarily white to grayish blue. Sometimes shades of yellow and red.	Primarily white or grayish white. Sometimes pale green or yellowish.
Flame color	Crimson	Crimson
Fracture	Uneven	Conchoidal
Hardness	3.0–3.5	3.5–4.0
Index of refraction	1.622–1.631	1.520–1.667
Luster	Vitreous, pearly on cleavage	Vitreous

Specific gravity	3.9–4.0	3.6–3.8
Streak	White	White
Theoretical strontium content	47.6%	59.3%
Transparency	Translucent to opaque. Rarely, nearly transparent.	Translucent to transparent.

celestite or strontianite appear as geodes in calcite, celestite veins in clays and carbonate rocks, and metasomatic bodies in carbonate rocks. One deposit of this type is identified near Münster, Germany. Volcanic–sedimentary deposits are associated with rhyolites, andesites, basalts, and their tuffs and tuffites. Strontianite is believed to be a secondary mineral formed through the weathering of celestite (Harben and Kužvart 1996).

United States

Although celestite deposits have been identified nationwide, domestic production has been very limited. During World War II, celestite was mined in California and Texas. Since 1959, all demand has been met from foreign sources. Only one U.S. company, Chemical Products Corporation (CPC), produces strontium carbonate—by far, the most important strontium compound. CPC uses the black ash method to convert imported Mexican celestite to strontium carbonate production at its 22-ktpy plant in Cartersville, Georgia. The company also produces strontium nitrate.

A few companies produce other minor strontium compounds from strontium carbonate. Mallinkrodt Inc. of St. Louis, Missouri, produces strontium chloride, and La porte Pigments Corp. of Beltsville, Maryland, produces strontium chromate. Other companies produce smaller quantities of other downstream strontium compounds.

In 1944, domestic strontium deposits were operated at the following sites: near Blanket in Brown County, Texas; in Nolan County, Texas; in the Fish Mountains in Imperial County, California; and near Ludlow, California (Gwinn 1944). At that time, the major use for strontium chemicals was for pyrotechnic applications such as signal flares and tracer bullets required for military applications. Immediately following World War II, this demand dramatically decreased, resulting in reduced domestic production of celestite.

Resources in the United States have been estimated at 3.2 Mt with an identified reserve base of 1.4 Mt. The reserve base figure includes material containing no more than 60% strontium sulfate, a much lower grade than specified by modern consumers. In addition to deposits mined in the early 1940s, celestite has been discovered in Arizona, Arkansas, Kentucky, Michigan, Missouri, New York, Ohio, Pennsylvania, Tennessee, Utah, and Washington (Schreck and Arundale 1959).

Other Countries

Huge deposits of high-grade celestite have been discovered throughout the world. In almost all instances, celestite deposits occur far from population centers in remote, undeveloped locations where inexpensive labor is a valuable for mining. World celestite production is listed in Table 2.

Detailed information on most world resources is not readily available. Many of the large deposits are in remote, sparsely inhabited areas, where very little exploration has occurred. Other known deposits are in countries where specific mineral information is not easily obtained.

Two types of strontium capacity exist. The first is ore production capacity in which celestite is mined and beneficiated for use or additional processing. The second, strontium compound production capacity, represents the size of the operations that convert strontium minerals (almost always celestite) through chemical reactions to other forms of strontium, including strontium carbonate and strontium metal. Strontium compound capacity is deemed the more important for several reasons. Essentially, all strontium is consumed in compound form, primarily as the carbonate and to a lesser extent as the nitrate. Strontium carbonate is also the intermediate product in production of downstream compounds. At least nine countries mined celestite in 2003, as shown in Table 2.

Table 2. Celestite: World production by country, * t

* World totals and estimated data are rounded to no more than three significant digits and may not add to totals shown.

† In addition to the countries listed, China and the Commonwealth of Independent States (CIS) produce strontium materials, but output is not reported quantitatively and available information is inadequate to make reliable estimates of output levels.

‡ Estimated.

§ Preliminary.

** Data are for year beginning March 21 of that stated.

†† Reported figure.

Virtually all of the celestite mined annually is consumed in the production of strontium carbonate and other strontium compounds. Very little strontium was consumed directly in the mineral form. Because most ore is produced for market by means of very simple sorting and beneficiation techniques, capacity can easily be raised to meet increased demand. Strontium carbonate production capacity is the limiting factor in strontium production, requiring more complicated and sophisticated processing facilities. Estimated strontium carbonate production capacity listed in Table 3 was compiled from reports cited in the following specific country sections.

Algeria

Celestite was mined in Algeria from the Beni Mançour surface deposit near Boira, although no production has been reported since at least 1996. The deposit was mined by Entreprise Nationale des Produits Non Ferreux et des Substances Utiles (ENOF) and was controlled by L'Entreprise Nationale de Développement Minières (SON AREM). In the past, as much as 3.6 ktpy was exported to nations in Eastern Europe and the former Federal Republic of Germany. Although the celestite was relatively low grade—only about 70% strontium sulfate—it contained low concentrations of barite, silica, gypsum, and iron, making it possible to concentrate the ore to acceptable levels using only gravity separation (Anon. 1988a). Reported reserves at Beni Mançour were more than 6 Mt of 70% strontium sulfate. ENOF was considering new production from the deposit to supply a possible domestic strontium carbonate plant whose output would be exported (Senouci, Nadir, and Houssa 2000).

Argentina

Although not a major producer of celestite, some is mined in Argentina. Little information about the Argentine strontium industry, other than production data, has been published for several years (Torres 2003). When detailed information was last reported in 1988, celestite mining was controlled by the Argentine Mining Union at the San Juan mine in the province of Mendoza. Celestite was identified at a few additional small mines, the Maria Del Carmen and Don Luis mines, also in Mendoza Province, and the Rayoso, Julio, Cerro Partido, and Llao mines in the province of

† Production was entirely from imported celestite.

‡ Strontium carbonate production capacity existed in these countries, but specific data are not available.

Neuquen. It is unlikely that production has occurred on a regular basis at these mines. Most Argentine production was exported to Brazil (Anon. 1988b).

Canada

Canada has produced celestite ore in the past from the McRae deposit, also known as the old Kaiser Celestite Mining Ltd. mine, at Enon, Cape Breton County, Nova Scotia. Timminco Ltd. of Toronto holds the mineral rights for this deposit. Exploration identified reserves of more than 1 Mt of celestite, with grades ranging from 60% to 65% strontium sulfate. Reopening the mine has been considered, but the low grade of the ore makes economic feasibility questionable. Other strontium deposits have been identified in British Columbia, Newfoundland, and Ontario, but none are as significant as the deposit in Nova Scotia (Dawson 1985). Celestite has not been produced in Canada for many years.

Timminco, the world's leading producer of strontium metal, produces strontium metal in Ontario from imported strontium carbonate. The company also produces strontium-aluminum master alloys, which Timminco advertises as the highest quality in the world, referring to their purity, low gas content, fast dissolution rate, low porosity, and precise weight. Timminco sells strontium as crowns, sections, and turnings, and in master alloys containing 90% strontium and 10% aluminum (Timminco 2000).

China

A long-time producer of celestite and strontium carbonate, China has dramatically expanded its carbonate capacity to reach more than 200 ktpy in 2003 from about 50 ktpy in 1995. Celestite production has not kept pace, and so China has become a major importer of celestite to supply its strontium carbonate plants. Strontium carbonate is used for televisions and magnets in China, but the majority of it is exported. Exports grew to 97 kt in 2002 from 42 kt in 1995.

Although China may have sufficient reserves to supply its domestic strontium carbonate plants, celestite concentrates vary from 80% to 85% strontium sulfate, much lower quality than prod-

ucts from deposits in Mexico, Spain, and Turkey. Celestite is produced from the Hechuan deposit in Sichuan Province and from the Lishui deposit in Jiangsu Province. Coope reported reserves to be nearly 30 Mt. Celestite is also produced in Henan Province (Harben and Kužvart 1996; Coope 2003). A strontium carbonate plant in Sichuan Province was the only one in the world based on strontianite. Technical problems hampered the success of the process, and the current status is unknown (Hong 1993).

Cyprus

Celestite was mined briefly in Cyprus starting in 1985 from a deposit near the village of Maroni near the southern coast of the island. Hellenic Mining Co. Ltd. operated the mine (Malinotis and Ilich 1986). The ore averaged about 54% strontium sulfate and, therefore, required beneficiation to make it marketable. The ore was beneficiated through a flotation process to reach 94% strontium sulfate. The reserves were reported to be 200 kt of celestite (Griffiths 1984). No production has been reported, however, since 1987.

Germany

Strontianite was produced sporadically from deposits in Westphalia. Celestite deposits have also been identified, but no strontium concentrates have been produced in Germany for nearly 50 years.

Solvay Barium Strontium GmbH (a subsidiary of Belgium's Solvay S.A.) operates a 150-ktpy barium and strontium carbonate plant at Bad Hönningen; the effective strontium carbonate capacity is about 70 ktpy. Solvay uses imported Spanish celestite as the raw material for its black ash strontium carbonate plant. Including its strontium carbonate plants in Italy, the Republic of Korea, and Mexico, Solvay is the world's largest strontium carbonate supplier (Houssa 1999).

Iran

Iran has a very large celestite deposit about 200 km southeast of Tehran in the northwestern part of the Dasht-e-Kavir salt desert. Average strontium sulfate values for the deposit have been reported at more than 91%, but the levels of barium sulfate and calcium sulfate are unfavorably high (Shiebel 1978). Iran Strontium Co. produces celestite concentrate from the Nakhjir deposit. Celestite reserves in Iran were reported to be about 3 Mt (Harben and Kužvart 1996; Regueiro 1998).

Italy

In the past, Mineral Chimica Farnesiana SpA in Tarquinia mined celestite near Rome. The product was 75% strontium sulfate and 5% barium sulfate, most of which was sold domestically. Annual production capacity at the mine was 7.3 ktpy (Anon. 1992). Production ceased in 1988. Celestite deposits have been identified on Sicily, but, because costs were high, production probably was restricted to material that was exported to Germany during World War II.

Solvay owns a plant in Massa that can produce barium or strontium carbonate. Its capacity is not known (Anon. 1999b).

Japan

Once a large producer of strontium carbonate from imported celestite, Japan's importance as a strontium compound producer has declined as production in the Republic of Korea and Mexico has increased. Four companies produced strontium carbonate from imported celestite, although up-to-date information on plant capacities and status are difficult to confirm. Capacity is believed to be about 20 ktpy. All celestite is imported. Honjo Chemical Corp. and Sakai Chemical Industries Co. operated strontium carbonate

production facilities and still offer strontium carbonate for sale. No current information is available for the other two companies.

Korea, Republic of

Celestite deposits have not been identified in the Republic of Korea, but its television industry consumes large quantities of strontium carbonate. Daehan Specialty Chemicals Co., Ltd., a joint venture between Solvay and Samsung Display Services, has produced strontium carbonate and barium carbonate since 1990 at its 40-ktpy plant in Onsan. The black ash process is used (Anon. 1999a).

Malawi

In 2002, Rift Valley Resource Development Ltd. conducted a feasibility study on the development of the Kangankunde strontianite/rare-earths deposit. The Malawian Geological Survey reported that the deposit contains 11 Mt of strontianite and monazite (a rare-earth mineral). Phase 1 of development would produce strontium carbonate for export and monazite concentrates that would be stockpiled for later phases of the project. Glass-grade strontium carbonate production was expected to be about 20 ktpy (Tassell 2002). The European Investment Bank and the Development Bank of South Africa funded the feasibility study (Saner 2002).

Mexico

Mexico is the world's largest celestite producer, and virtually all U.S. imports of celestite since 1991 have been from Mexico. Although mining methods are very simple, mining efficiency has increased, and improved mining methods have expanded productivity at several small operations. The largest Mexican celestite producer is Minas de Celestita SA de CV, a company that controls celestite reserves in Coahuila State of between 6 Mt and 6.5 Mt of proven and inferred ore. Cia. Minera La Valenciana SA de CV (CMV) operates the San Agustín mine, the single largest mine in Mexico. As much as 1 Mt of celestite has been mined from this deposit that may be nearing depletion. Minera La Roja, SA de CV is the third major celestite producer in Mexico.

Minas de Celestita operates mines that supply CPC's operation in Mexico and the United States exclusively. In addition to its Georgia plant, CPC operates a 50-ktpy-strontium carbonate plant in Reynosa, Tamaulipas State. CMV's mine provides the celestite to operate its own 50-ktpy-strontium carbonate plant in Torreón. Solvay Química y Minera, SA de CV (a subsidiary of Solvay), uses celestite produced by Minera La Roja at its 27-ktpy strontium carbonate plant in Monterrey (Moore 2002). Mexico is the largest strontium carbonate producer in the world, and the vast majority of all U.S. strontium imports, including minerals and compounds, come from Mexico.

Pakistan

Recent reports describing the strontium industry in Pakistan are unavailable, although production data are reported annually. Older publications reported celestite production from two mines, one near Dawood Khail and one near Karachi (Anon. 1988c). Tawakkal Mineral Exports Corp. recovered celestite from these mines in the Dadu District of Sind Province. No beneficiation was necessary to produce 95% strontium sulfate. Reserves of celestite have not been reported at this location (Griffiths 1987). Other deposits, with 500 kt of reported reserves, have been identified in the Punjab Province (Anon. 1992).

Russia and the Commonwealth of Independent States

Very little is known about production of strontium minerals in this part of the world. Deposits are known in the following regions: the

Karakum Desert, Zaunguz Plateau; near Bashkir; in the Pinega Area, Archangel Province; near Yakutsk, eastern Siberia; and in Turkestan from eastern Fergana to the shores of the Caspian Sea and from southeastern Bucharra to the shores of the Sea of Aral. Celestite also has been found in the cap rocks of the Romy and Isachkov salt domes. Reserves are believed to be very large, but the ore grade is probably not high (Kishimoto 1982). Few details are available concerning the production of celestite or strontium carbonate since the breakup of the Soviet Union. Celestite was reportedly produced from two deposits in Turkmenistan (Regueiro 1998).

Spain

As the world's second largest celestite producer, Spain mines celestite at two locations. The Montevive deposit, which is operated by Canteras Industriales SL, has been in production since about 1940, and the Escúzar deposit, which is mined by Solvay Minerales SA (a subsidiary of Solvay), has been in production since 1989 (Griffiths 1992; Coope 1997). The Montevive deposit contains an estimated 8 Mt of reserves grading 80% strontium sulfate. Selective mining, hand sorting, crushing, and granulometric sorting results in a product containing 95% strontium sulfate. A mobile secondary screen separates a second 90% strontium sulfate product; additional concentration facilities are planned. Much of the Montevive production is exported to China. The Escúzar deposit has reserves estimated at about 4 Mt of 54% strontium sulfate. More complicated beneficiation techniques than those used at Montevive produce a 94% strontium sulfate concentrate. Most of this material is exported to Solvay in Germany or Daehan in the Republic of Korea (Regueiro 1998).

Promotora de Industria del Sur (Prominsur SA) produced strontium carbonate and strontium nitrate at a combined facility near Granada until 1991 when market conditions forced its closure. The plant had a theoretical design capacity of 8 ktpy of carbonate but never reached that level of production. Strontium carbonate was produced by the soda ash method. The plant also had an unattained production capacity of about 3 ktpy of nitrate (Griffiths 1992). Químico Estroncio (a joint venture of Minas de Almadén y Arrayanes SA, Fertiberia SA, and Erkimia SA) built a 20-ktpy strontium carbonate plant in Cartagena that opened in 2000. The plant was to use an unusual technology for strontium carbonate production, and it seems to have experienced some technical problems scaling up to commercial production. Significant production has not been achieved, although Fertiberia, the new owner of the plant, continues to work toward successful operation (Coope 2003).

Turkey

A long-time celestite producer for the export market, Barit Maden Turk AS sold most of its production to the Republic of Korea and China. Barit Maden produces celestite from a mine near Akkaya in Sivas Province. Run-of-mine ore is gravity-separated to produce a concentrate with a minimum of 95% strontium sulfate. Because of the harsh winters in the region, the mine can be operated only seasonally, from May to October. Identified reserves have been placed at 550 kt, and further reserve potential was estimated to be greater than 2 Mt (Karayazici 1987).

As of 1999, the company was building its own strontium carbonate plant; progress on this project is unknown. In preparation for its expansion into carbonate production, Barit Maden built a carbon dioxide plant that was profitable even before the strontium carbonate facilities were completed. Its high-quality celestite resources and the in-house carbon dioxide supply contributed to Barit Maden's confidence that its strontium carbonate would be high quality and cost-competitive with other producers (Houssa 1999).

United Kingdom

The world's largest supplier of celestite from around the time of World War I until about 1968, Bristol Minerals Co. Ltd. mined deposits in the Bristol area. The ore was crushed, washed, and graded to achieve a product with 95% strontium sulfate. One of the few sites in the world where celestite deposits were in populated areas, the British deposits were encroached on by large-scale housing developments, which limited exploitation of the minerals (Griffiths 1984). Mining ceased in 1991 when the accessible reserves were exhausted. For a short time following the closure of the mine, Bristol Minerals continued to reprocess mine tailings that were sold to Solvay in Germany (Griffiths 1992).

Other Countries

Strontium minerals have been identified in other countries, but the deposits were not commercially developed on a large scale. Celestite occurs in Australia, France, India, Morocco, Poland, and Tunisia (Schreck and Arundale 1959; Harben and Kužvart 1996).

PROCESSING

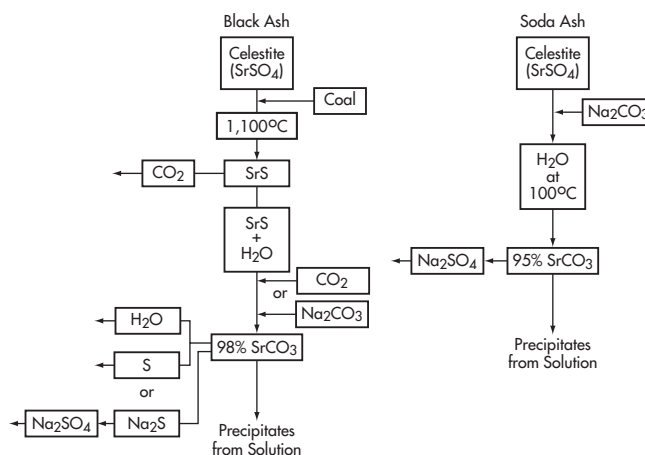

Strontium commonly occurs with barium and calcium, two elements with properties very similar to strontium, making separation difficult. Because removing many impurities from celestite is difficult and energy intensive, strontium chemical producers require that material contain at least 90% strontium sulfate. Most of the operating celestite facilities in 2003 produced sufficient supplies with only minimal processing necessary to achieve acceptable specifications. Hand sorting and some washing are adequate at many strontium mines to produce celestite that meets customer specifications. A few operations use froth flotation or gravity separation to beneficiate their ore.

Strontium carbonate is the most important strontium compound, and two methods are used to produce it. The black ash and soda ash methods are the two most common recovery techniques.

The black ash method, known alternatively as the calcining method, produces chemical-grade strontium carbonate, which contains at least 98% strontium carbonate. This method received its name because, in the first step in the procedure, the crushed and screened celestite is mixed with powdered coal, making a black mixture. The mixture is then heated to about 1,100°C, expelling oxygen in the form of carbon dioxide from the insoluble strontium sulfate to form water-soluble strontium sulfide. Strontium sulfide is dissolved in water, and the resulting solution filtered. Carbon dioxide then is passed through the solution or soda ash is added. Either compound provides the necessary carbon and oxygen for strontium carbonate to form and precipitate from the solution. The precipitated strontium carbonate is then removed from the solution by filtering and is dried, ground, and packaged. The sulfur released in the process is either recovered as elemental sulfur or in other by-product sulfur compounds. A simplified flow chart illustrates both processes in Figure 1.

In the soda ash method, ground celestite is washed and most of the water removed. The thickened mixture is then mixed with soda ash and treated with steam for 1 to 3 hours. During this time, celestite and soda ash react to form strontium carbonate and sodium sulfate. Sodium sulfate is water soluble, making it possible to separate the insoluble strontium carbonate by centrifuging. Although the soda ash method is a simpler process than the black ash process, the lower grade of the product makes it the less preferred method of recovery. The black ash method is more common for strontium carbonate production.

Other strontium chemicals are produced from strontium carbonate. Strontium nitrate is produced through the reaction of

Adapted from Ober 1989.

Figure 1. Simplified flow chart of the two methods for strontium carbonate production

strontium carbonate with nitric acid. Other strontium chemicals are produced through similar procedures of reacting strontium carbonate with the acid appropriate for the desired result. Some of the acids used are bromic, hydrochloric, oxalic, stearic, and tartaric (Schreck and Arundale 1959).

Strontium ferrite magnets are prepared by mixing strontium carbonate with iron oxide and crystal growth inhibitors and presintering at between 1,000° and 1,300°C (Reynolds 1980). Strontium titanate is formed by reacting a mixture of high-purity strontium carbonate and titanium dioxide (Griffiths 1985).

Strontium metal can be produced in two ways. The more common method is through the thermal reduction of strontium oxide and aluminum metal, subsequent distillation under high vacuum, and condensation of metallic strontium on a cooled plate. The other method is electrolysis of a fused bath of strontium chloride and ammonium chloride or potassium chloride (Schreck and Arundale 1959).

ECONOMIC FACTORS

Uses

Approximately 80% of all strontium is consumed in ceramics and glass manufacture, primarily in television faceplate glass and ceramic ferrite magnets (Table 4), and smaller amounts in other ceramic and glass applications. In the past 20 years, color television production has become the major consumer of strontium. Because of the unique properties that strontium compounds possess, including the ability to block x-rays, magnetic characteristics, and the brilliant red flame when burned, technologies have been developed that take advantage of those properties for specific applications. All color televisions and other devices containing color CRTs sold in the United States are required by law to contain strontium in the faceplate glass of the picture tube. Strontium blocks x-rays better than barium, which was previously used, and, although lead is a better x-ray barrier than strontium, it causes a brownning of the glass. Major manufacturers of television picture-tube glass incorporate about 8% strontium oxide, by weight, in their glass faceplate material. The strontium is added to the glass melt in the form of strontium carbonate, and during processing it is converted to strontium oxide. In addition to blocking x-rays, the strontium improves the appearance of the glass, increasing the brilliance and improving the quality of the picture (Wagner 1986).

Table 4. U.S. estimated percentage distribution of primary strontium compounds, by end use

End Use	1999	2000	2001	2002	2003

Other	4	2	2	3	3
Total	100	100	100	100	100

Source: Ober 2004.

Trends in CRT production show a shift to larger, flatter tubes that require thicker glass and therefore more strontium. Although the U.S. television industry is considered mature, the demand for replacement TVs as well as for additional sets in large numbers of households continues. The rising sales of personal computers and sophisticated, computerized instrumentation increased the demand for strontium in color monitors for these devices. The increasing popularity of flat-screen devices for television and computer monitors is, however, starting to adversely affect the consumption of strontium in CRT applications. Flat-screen technology, such as liquid crystal displays (LCDs) and plasma devices, do not require strontium. These devices are becoming more affordable, causing decreased demand for more traditional CRTs and thus lower demand for strontium carbonate.

The presence of strontium in other glass applications improves the brilliance of the glass and the quality of certain ceramic glazes as well as eliminates the toxicity that may be present in glazes containing lead or barium. One high-tech strontium ceramic is strontium titanate, which is sometimes used as a substrate material for semiconductors and also in some optical and piezoelectric applications.

Permanent ceramic magnets are another large end use for strontium compounds, in the form of strontium ferrite. When these magnets were first developed, they were used primarily as magnetic closures for refrigerator doors. Applications have expanded to include extensive use in small direct current (DC) motors, especially for automotive applications such as windshield wiper motors, as well as loudspeakers, other electronic equipment, toys, and magnetically attached decorative items.

Strontium ferrites are used in permanent ceramic magnets because they have high coercive force, high thermal and electrical resistivity, and are chemically inert. They retain their magnetism well, are not adversely affected by electrical currents or high temperatures, and do not react with most chemical solvents. Other properties that make the strontium magnets more attractive for specific applications are their resistance to demagnetization and lower density, making them more desirable in applications where weight is a factor (Haberberger 1971). Barium or lead can replace the strontium in ferrite magnets, but strontium ferrites have been found to possess the best combination of properties necessary for superior magnets.

One of the most consistent and continuing applications for strontium has been in pyrotechnic devices. Strontium burns with a brilliant red flame, and no other material has been found to be better in this application. The strontium compound used most frequently in pyrotechnic devices is strontium nitrate. Some strontium compounds are slightly hygroscopic, but strontium nitrate takes on very little water and imparts the desired brilliant red. Strontium carbonate, strontium oxalate, strontium sulfate, and strontium chlorate are used in pyrotechnic applications, but strontium nitrate is used in significantly larger quantities than any of them. Pyrotechnic devices

are used in military and non-military applications. Military pyrotechnic applications that contain strontium include tracer ammunition, military flares, and marine distress signals. Nonmilitary applications include warning devices and fireworks (Conkling 1981). The strontium content in military flares can be up to 40% by weight and about 20% for Roman candle fireworks (Harben and Kužvart 1996).

Strontium is used to remove lead impurities during the electrolytic production of zinc. Zinc used in die-casting alloys is required to contain less than 0.003% lead. The addition of strontium carbonate in sulfuric acid to the electrolyte reduces the lead content of the electrolyte and of the zinc that is deposited on the cathode (Bratt and Smith 1963).

Adding strontium chromate to paint creates a coating that is resistant to corrosion and effective for aluminum, most notably on aircraft fuselages and ships. These paints are used to some degree on aluminum packaging to prevent package corrosion. The nitrate and chloride contents of strontium chromate paint pigment are very strictly controlled to prevent corrosion (Anon. 1992).

Metallic strontium is a small part of total strontium consumption. Small amounts of strontium are added to molten aluminum to improve the castability of the metal, making it much more suitable for casting items that have been traditionally made from steel. The addition of strontium to the melt improves the machinability of the casting. Although aluminum parts were impractical before modification techniques were developed, the use of cast aluminum, rather than steel parts, has become common in the automotive industry. The resulting reduction in the weight of the automobile helps to improve the energy efficiency of the cars incorporating these parts (Lidman 1984).

At the present time, other strontium end uses consume only small amounts of strontium and strontium compounds. Strontium chloride is used in toothpaste for sensitive teeth. For this application, the content of impurities must be strictly controlled, with limits for some of them in the parts-per-million range. Strontium phosphate is used in the manufacture of fluorescent lights, and the entire range of strontium chemicals is used in analytical chemistry laboratories.

Prices

Published prices for celestite and strontium compounds are not available. Tracking the customs values of various imported material is the best available way to evaluate trends in strontium pricing. Although the customs values may not represent the exact price any specific consumer pays for celestite or another strontium product, they are a good basis for estimating and evaluating trends in pricing. The average customs value for celestite imported from Mexico, the sole source of U.S. celestite imports in 2003, was about \$57/t, a decrease of nearly 29% since 1990 when the customs value was \$80/t. In 2003, the average unit customs value of imported strontium carbonate was \$0.48/kg and the corresponding value for strontium nitrate was \$2.95/kg. Strontium carbonate values have been relatively steady or lower in recent years, and strontium nitrate prices have been increasing. Table 5 lists the average value of imported celestite, along with other important strontium statistics.

Foreign Trade

The United States has never been a major exporter of strontium compounds. The U.S. Bureau of Mines published estimated export statistics for the first time in 1985 at a total of about 21 t of strontium exports. The U.S. Census Bureau reported strontium exports for the first time in 1990 including the two categories of strontium carbonate and strontium oxide, hydroxide, and peroxide that totaled 2.88 kt. Exports peaked in 2000 at 7.18 Mt (Table 6). Since that time, exports

† Customs value.

have fallen sharply with total exports of 1.03 Mt in 2003, an 86% decrease in 3 years (Table 6). This is a result of increased production worldwide, which created additional competition for U.S. exports.

Much larger quantities of strontium products are imported into the United States than are exported, as shown in Table 7. Imports of celestite have decreased significantly to 2.32 kt in 2002

from 31.3 kt in 1999. Strontium carbonate is the most important strontium compound that is imported, consistently representing at least 97% of total imports of strontium compounds. Mexico is the source of 94% of strontium carbonate imports. Strontium compound imports were more than 22% lower in 2003 at 39.2 kt than they were in 2000 when they reached 50.5 kt.

PROBLEMS AND FUTURE TRENDS

Environmental Problems

Not all strontium is beneficial. Strontium-90, a radioactive isotope of strontium, is a component of nuclear waste from reactors and nuclear fallout. It presents special problems for waste disposal and storage because it generates a significant amount of heat as it decays. When released into the atmosphere through nuclear testing or accidents, it easily enters the food supply via milk and vegetables because it is so chemically similar to calcium. Recent reports on possible terrorist activities have suggested that strontium-90 from spent nuclear fuel rods could be one component of a dirty bomb, in which a conventional explosive device could be used to spread radioactive material, creating a contaminated area that could be difficult to clean up.

Scientists at Argonne National Laboratory developed a process for removing strontium-90 from liquid nuclear waste. The method dissolves more than 99.999% of the strontium-90 from the waste stream in a special solvent. Pure strontium-90 is then removed from the solvent with water or a dilute acid. The recovered strontium-90 could be used in radioisotopic thermal generators that are found in devices such as harbor markers, which require long-lasting, unattended power supplies (Worthy 1990).

Future Trends

Sales of televisions and computer monitors in the United States will continue to influence U.S. strontium consumption significantly, although increased imports of faceplate glass and decreased growth in CRT demand will contribute to lower domestic consumption of strontium compounds. As long as CRTs are used in television and computer monitors, world consumption should continue, but at lower growth rates than those seen in recent years. Ferrite magnet markets are expected to be strong. Growth in other markets will probably continue at the current slower rate. Improved economic conditions worldwide could spur additional growth in demand for strontium carbonate.

Flat-screen display systems for televisions and computer monitors have threatened to replace CRTs for many years, but the cost of the new technology has restricted growth. Flat panels, however, have begun to have an impact on the CRT market, and the flat-panel market is growing at a much higher rate than that of the CRT market. Improvements have increased the likelihood that the large flat screens that use either LCDs or plasma technology will replace bulkier CRTs. LCDs, which are smaller and use less energy than plasma display systems, seem to be filling the market for relatively small, flat displays, such as those required for portable computers. The market for LCD materials is expected to grow at a rate of 16.4% per year through 2005 (Markarian 2002).

Worldwide, about 150 million CRTs per year are produced. In 2001, the last year for which such data were available, about 300,000 plasma displays were sold; by 2005, sales were expected to approach 4 million units, a 13-fold increase (Tremblay 2002). Plasma technology is more common for large, high-definition televisions with screens up to 60 in. and wider (Tremblay 1999). Neither LCD or plasma technology requires strontium carbonate in the glass, but both have been too expensive to make serious inroads in the domestic CRT market until now. In 2000, a 20-in. flat-screen television in Japan cost around \$2,500, significantly more than a comparable device with a CRT. The costs of larger plasma screens (usually between 37 and 60 in. diagonally) were between \$10,000 and \$14,000 (Landers 2000). In 2002, prices were reported to be between \$6,000 and \$10,000 for similar items—a significant decrease, but still quite expensive (Tremblay 2002). Major retailers,

however, were offering some plasma display systems at \$3,000 and below. In 2004 and 2005, the price for similar items was under \$2,000. As these new display systems become more economically attractive to the public, CRTs will become obsolete, and so will the major market for strontium carbonate.

ACKNOWLEDGMENTS

This material was adapted from the chapter on strontium from the 2003 U.S. Geological Survey *Minerals Yearbook*. Hoa Phamtrang, statistical assistant, assisted in the preparation of domestic survey data, and Regina R. Coleman, international data coordinator, prepared the international production table.

The sole U.S. strontium carbonate producer voluntarily provided domestic production data to the U.S. Geological Survey. Production and stock data, however, were withheld from publication to avoid disclosing company proprietary data.

Sulfur

Joyce Ober

INTRODUCTION

Sulfur, a nonmetallic element, is widely distributed in nature and has great industrial and economic importance. It is the thirteenth most abundant element in the earth's crust (0.06%) and an important constituent of animal and plant life (Bush and Semrad 1996).

Sulfur has been known and used since ancient times for several medicinal and industrial uses. In modern times, most sulfur is used to generate sulfuric acid, which is a component of a wide variety of industrial processes, particularly the production of fertilizer. Because of this, sulfuric acid (and hence sulfur) consumption often has been regarded as a good indicator of a nation's industrial development.

In the past, sulfur was mined from surface occurrences in several geologic environments and was used in relatively small amounts. Over time, the uses of sulfur and sulfuric acid expanded, as did the need for larger quantities of these commodities. Sulfur is now mined from underground deposits; a much larger quantity, however, is recovered as a by-product from a number of industrial processes.

Sulfur resources are abundant and widespread, but prevailing prices and extraction technologies constrain the extent to which they can be classified as reserves. At present, sulfur can be economically mined from very few deposits. Most of the sulfur that is currently produced comes from natural gas and petroleum deposits, making it difficult to formulate reliable reserve data.

The sulfur industry is roughly divided into two sectors: voluntary (or discretionary) and involuntary (or nondiscretionary). In voluntary production, mining sulfur or pyrites is the sole objective, and the recovery of the resource is as complete as economic conditions will allow. During involuntary production, sulfur or sulfuric acid is recovered as a by-product and the quantity of the output is dictated by the demand for the primary product and the environmental regulations mandating sulfur removal from the finished products and emissions. Involuntary sulfur is often referred to as recovered sulfur and the acid produced is known as by-product sulfuric acid.

In the early sulfur industry, voluntary sulfur was the sole source of sulfur production. Small quantities of involuntary sulfur in the form of sulfuric acid began to appear early in the 20th century, and by-product elemental sulfur was reported in the late 1930s. Recovery of elemental sulfur from natural gas processing and petroleum refining first overtook sulfur mining as the dominant source in the United States in 1982, and its importance has

increased steadily since that time. Recovered sulfur dominates the world markets. In 2003, mined sulfur was less than 3% of total elemental production worldwide. U. S. sulfur mining ceased completely in 2000. Poland continued to mine sulfur at one location, and some sulfur may have been mined in Iraq.

Sulfur Sources

Barker (1983) describes sulfur sources as follows:

- Combined sulfur—sulfur that occurs in nature combined with other elements, commonly referred to as sulfides and sulfates
- Cupriferous pyrites—pyrite containing minor amounts of copper sulfides. The most common is chalcopyrite, a sulfide of copper and iron with the formula CuFeS_2 or $\text{Cu}_m\text{Fe}_n\text{S}_{(m+n)}$.
- Hydrogen sulfide (H_2S)—a colorless, flammable, toxic gas that may occur in petroleum and natural gas
- Involuntary sulfur—sulfur produced as a by-product in response to legislative or process mandates
- Native sulfur—sulfur that occurs in elemental form in nature
- Nonferrous metal sulfides—copper, lead, zinc, nickel, and molybdenum sulfides that are processed for their metal content
- Organic sulfur—complex organic sulfur compounds that occur in petroleum, coal, oil shale, and tar sands
- Pyrites—metallic-looking sulfide minerals of which iron pyrites (pyrite) is the most common, and includes marcasite, and pyrrhotite
- Sulfate sulfur—sulfur combined as SO_4^{-2} as contained in anhydrite, gypsum, and many other minerals
- Voluntary sulfur—elemental sulfur or pyrites produced in response to market demand

Basic Sulfur Products

Barker (1983) describes basic sulfur products as follows:

- Acid sludge—contaminated sulfuric acid, frequently the result of petroleum alkylation, usually returned to acid plants for reconstitution
- Bright sulfur—crude sulfur free of discoloring impurities; bright yellow in color
- Brimstone—common name for sulfur; synonymous with crude sulfur
- Broken sulfur—solid crude sulfur crushed to -8 in.

- By-product sulfuric acid—sulfuric acid produced as a by-product of a metallurgical or industrial process, generally relating to combined sulfur sources
- Crude sulfur—commercial nomenclature for elemental sulfur that is 99.0% to 99.9% pure and is free from arsenic, selenium, and tellurium
- Dark sulfur—crude sulfur discolored by minor quantities of hydrocarbons, ranging up to 1.0% oil and carbonaceous material
- Elemental sulfur—processed sulfur in the elemental form produced from native sulfur or combined sulfur sources, generally with a minimum sulfur content of 99.5%
- Formed sulfur—elemental sulfur cast or pressed into particular shapes to enhance handling and to suppress dust generation and moisture retention
- Frasch sulfur—elemental sulfur produced from native sulfur sources using the Frasch hot water mining process
- Liquid sulfur—synonymous with molten sulfur
- Liquid sulfur dioxide—purified sulfur dioxide compressed to the liquid phase
- Molten sulfur—crude sulfur at a sufficiently high temperature to keep it from solidifying, thus maintaining a liquid (molten) state
- Prilled sulfur—solid crude sulfur that is cooled in air or water to form small spheroids
- Recovered sulfur—elemental sulfur produced as a by-product of natural gas processing, petroleum refining, water gas, and other fuel gases
- Slated sulfur—solid crude sulfur in the form of slate-like lumps, produced by allowing molten sulfur to solidify on a moving belt
- Specialty sulfur—prepared or refined grades of elemental sulfur that include amorphous, colloidal, flowers, precipitated, wettable, flour, and paste sulfur, usually used in elemental form
- Sulfur ore—unprocessed ore containing native sulfur
- Sulfuric acid—sulfuric acid of commerce as produced from all sources of sulfur, generally reported in terms of 100% H_2SO_4 with 32.69% sulfur content

Ober (2004) estimates that nearly 62 Mt of sulfur was mined or recovered as a by-product in 2003 (Table 1). Production was reported in more than 75 countries, 24 of which accounted for almost 93% of the production, each producing more than 500,000 t. The United States and Canada were the leading producers, each with more than 9 Mt of production in 2003.

Sulfur occurs naturally as a native element in subsurface deposits within salt domes and bedded evaporites (anhydrite and gypsum), many of which were mined in situ using the Frasch mining method. Such deposits are thought to form through the actions of bacteria in the presence of hydrocarbons and calcium sulfate, and are termed *bioepigenetic* deposits. In 1974, the year in which Frasch and other native sulfur production was at the highest historical levels, voluntary elemental sulfur sources supplied 35% (about 18 Mt) of the total world sulfur demand. Since that time, its importance has decreased dramatically, accounting for less than 3% of the total production in 2003 (Tables 1 and 2).

Bioepigenetic sulfur sources constitute most of the voluntary elemental sulfur production. Large bioepigenetic deposits have been exploited in the United States, Mexico, Poland, Iraq, Russia, Ukraine, and other former Soviet republics. Poland is the only major

sulfur producer that continues to produce Frasch sulfur. Iraq could potentially produce significant quantities of Frasch sulfur, but the situation in that country has been difficult to pinpoint since the 1990 Iraqi invasion of Kuwait and the subsequent wars and sanctions.

Native sulfur also occurs in solfatara-type deposits associated with volcanism and recent hydrothermal activity. These deposits are common in volcanic regions such as the western United States, Central America, the Andes, and the Philippines. Volcanic deposits are often contaminated with toxic elements, and so are rarely used except for nonagricultural local consumption.

Sulfur also occurs in combination with base metals as ferrous sulfides (pyrites) and nonferrous sulfides, from which sulfur or sulfuric acid is produced as a primary product or by-product. The importance of this source of sulfur has decreased in recent years, and in 2003 it supplied about 7% (less than 5 Mt) of the total demand for sulfur and sulfur compounds. China and Finland are the only major sulfur-producing countries where the major sulfur source is pyrites (Table 1).

Large quantities of sulfur are present in natural gas and petroleum as hydrogen sulfide and organic compounds from which elemental sulfur is commonly recovered. Sulfur recovered from natural gas and petroleum refining supplied almost 70% (about 43 Mtpy) of worldwide demand in 2003. In the United States, fuel processing plants accounted for 93% of the total output of sulfur in all forms. Ten countries recovered more than 1 Mt of elemental sulfur from fuel processing in 2003. They were, in decreasing order of production, the United States, Canada, Russia, Saudi Arabia, Japan, the United Arab Emirates, Germany, Kazakhstan, Iran, and Mexico.

Sulfur also occurs in organic form in coal, oil sands, oil shale, and tar sands. Canada is the only significant producer from this source, but that production is included with other fuels. Oil sands represent a potentially large source for recovered sulfur, especially in Canada. The province of Alberta has huge deposits of oil sands with estimated reserves of 300 billion bbl of recoverable crude oil that also contain 4% to 5% sulfur (Stevens 1998). The Athabasca oil sands are a mixture of sand, water, clay, and bitumen (a naturally occurring viscous mixture of heavy hydrocarbons). Because of its complexity, bitumen is difficult or impossible to refine at most oil refineries. It must be upgraded to a light-oil equivalent before further refining, or it must be processed at facilities specifically designed for processing bitumen. Oil sands with more than 10% bitumen are considered rich; those with less than 7% bitumen are not economically attractive (Anon. 1999a).

Enormous amounts of sulfur are present as sulfate (anhydrite and gypsum) in evaporite basins throughout the world, but economic methods have not been developed to recover sulfur from sulfate.

Commercial grades of elemental sulfur are classified as crude (run-of-mine, bright, or dark) and recovered. Both types of elemental sulfur are shipped in liquid or solid form, and are guaranteed to be 99.5% pure. The only significant impurity is usually carbon, present as hydrocarbons dispersed throughout the sulfur (dark sulfur may contain up to 0.3% carbon). Most end uses require relatively pure sulfur free of contaminating elements such as arsenic, selenium, and tellurium.

Most elemental sulfur in the United States is marketed in the liquid state. In international trade, sulfur is generally shipped as broken or formed sulfur. Formed sulfur (prills, slates, etc.) is preferred to broken sulfur because it causes fewer dust problems. Fine sulfur dust particles are difficult to contain and can be blown great distances on the wind. In addition to contaminating the area adjacent to the production locations, contamination can be a problem

along rail lines and at port facilities. Of even more concern than the dust contamination is the hazardous nature of sulfur dust. Finely divided sulfur presents explosive and fire hazards, and the sulfur dioxide (SO₂) generated by such a fire is toxic (West 1966). Specialty grades (such as refined sulfur of various shapes and sublimed sulfur) are prepared from commercial grades and distilled sulfur.

Sulfuric acid may be sold at various strengths, but it is generally marketed at 100 %. Acid is generally shipped at 66° Bé (93 % H₂SO₄), as 98% acid, or as 20% to 22% fuming oleum, which is sulfur trioxide dissolved in sulfuric acid (sulfuric acid strength is reported as a function of its specific gravity, reported in degrees Baumé, which is an arbitrary scale). In general, the specific gravity of

sulfuric acid increases as the concentration increases until it reaches 98% acid, at which point the specific gravity remains relatively constant as the concentration continues to increase (Anon. 1961).

HISTORICAL BACKGROUND

Sulfur has been known and used by humans since at least 4000 BC as a pigment, as a fumigant, and for medicinal and religious purposes (Haynes 1959). Earlier peoples throughout the world probably used sulfur as well, but sulfur's rapid oxidation in surface environments tends to remove it from the archaeological record.

As early as 2000 BC, the Egyptians used sulfur as sulfur dioxide to bleach linen textiles (Morse 1991). During the Peloponnesian War, in the 5th century BC, the Greeks may have employed the first chemical weapon when they burned a sulfur-pitch mixture to generate suffocating gases (Bauman 2001). The Romans used sulfur to create incendiary weapons, and they mined much of the sulfur they used from open cuts and shallow underground mines in the evaporite-hosted stratiform deposits in Sicily (Ellison 1971). The Romans also mined sulfur at other sites in their empire, such as in present-day Syria. Alchemists probably produced the first sulfuric acid around 700 AD.

The early uses of sulfur were relatively limited and only small quantities were mined. The invention of gunpowder by the Chinese in the 10th century eventually led to its widespread use in warfare and made sulfur an important mineral commodity. Some accounts suggest that gunpowder first was used in the West at the Battle of Crecy (1346) during the Hundred Years' War between England and France (1337 to 1453), and its introduction led to profound social and political changes in Europe. During this time, the Sicilian sulfur deposits continued to satisfy European demand.

Early in the 17th century, Johann Glauber, a German alchemist, accidentally discovered a process for making sulfuric acid by burning sulfur and niter (potassium nitrate) under a glass bell. Glauber's process was destined to become the cornerstone of the sulfuric acid industry, although at the time, sulfuric acid was generally used only for medicinal purposes. As others reproduced Glauber's efforts, and sulfuric acid production increased, industrial uses for sulfur developed and expanded. An English physician, John Roebuck, began manufacturing large quantities of sulfuric acid using a less expensive lead-lined container, and soon similar acid manufactories appeared. Because it is the cheapest and most versatile of the mineral acids, sulfuric acid became the workhorse of numerous chemical industries. By 1820, there were 23 acid plants in England alone (Haynes 1959). The first American acid production was in 1793.

The Sicilian sulfur deposits continued to supply much of the world's sulfur, but an attempt by French controlling interests in

1838 to stabilize the price of Sicilian sulfur at a high level led to the use of other sources of sulfur for the production of sulfuric acid. In 1833, a French chemist, Michel Perrett, developed a reasonably economical method of obtaining sulfur dioxide by roasting pyrites. His invention led to the development of a rotary furnace in 1870 that made pyrites a profitable raw material for acid. By 1880, sulfuric acid throughout the world was produced from pyrites, except in the United States where import tariffs on iron and copper prevented the shift from native sulfur. These import tariffs were removed in 1890 and 1894, respectively, and by 1900 pyrites had become the principal acid-making material in the United States.

Native sulfur deposits were known in North America, and several attempts were made to mine sulfur from salt-dome cap rock in Louisiana between 1870 and 1890 using conventional underground mining techniques. These efforts were frustrated by the nature of the sulfur ore and the overlying strata. In 1894, Herman Frasch developed a method of mining sulfur in situ using hot water and compressed air. Sulfur was first commercially obtained using the Frasch method in 1895 by the Union Sulphur Company at Sulphur Mines dome, Calcasieu Parish, Louisiana. The Frasch method was also employed in 1912 at Bryan Mound, Brazoria County, Texas, and later at many other domes (Ellison 1971; Halbouty 1979).

Shipping problems during World War I, and a growing preference for brimstone over pyrites in the contact process of acid production (first developed in the 1880s to generate larger quantities of high-strength acid), led to expanded use of Frasch sulfur. By 1919, 48% of American acid production used brimstone; by 1929, 69% came from this source (Haynes 1959).

World War II disrupted sulfur production and transportation outside North America, and recovery after the war was slow. Foreign consumers became more dependent on U.S. Frasch producers as they attempted to rehabilitate and expand their acid industries.

In 1950, Frasch sulfur from the U.S. Gulf Coast and sulfuric acid from pyrite-roasting plants in Europe were the major sources of the western world's sulfur. Competition from low-cost U.S. mines caused a rapid decline in sulfur production in Italy.

A supply shortfall during the Korean War led to short-lived controls imposed on the industry by the U.S. government. The controls were lifted after the cessation of hostilities. New mines were opened at several sites at about the same time. Producers opened new mines in the United States at Garden Island Bay and Damon Mound, and Mexico entered the Frasch market with production from San Cristobal in 1954 (Salas 1991). Also of great significance was the expansion and accelerated growth of recovered sulfur production in Canada, beginning at about this same time. Recovered sulfur production began in France in 1957, and Texasgulf Inc. opened the world's first liquid sulfur terminal in 1958 (Barker 1983; Giusti 1984).

The first Frasch sulfur from the huge deposits in Poland reached the market in 1960. Canadian and French recovered sulfur production continued to expand, and the U.S. share of world exports fell 19% in 4 years to 31%. Mexico surpassed the U.S. export tonnage in 1964. Additional Frasch mines were opened in Poland in 1966 and 1967, and the Duval Corporation discovered the large deposit at the Culberson mine in western Texas in 1967. As time progressed, recovered sulfur output exceeded Frasch sulfur output, even with the opening of the Frasch mine at Mishraq, Iraq, in 1972.

Price offensives by the oil and phosphate cartels in 1974 and 1975 led to recession and the drawdown of existing sulfur stocks. This resulted in a major cutback in the United States and Mexico, and the beginning of a gradual decline in North American Frasch production that continued until 2000, when North American production ceased entirely.

The three historical leaders in mined sulfur production in the United States were Freeport Sulphur Co., Pennzoil Sulphur Co., and Texasgulf (Lou ghbrough 1991). Over time, each company operated multiple Frasch mines and was notable for different reasons. Freeport, the last U.S. Frasch producer when it closed its Main Pass mine in 2000, operated more conventional salt-dome deposits, but was unusual in that the company's last mines were developed on platforms in the Gulf of Mexico. Pennzoil adapted the Frasch process to produce sulfur from bedded evaporite deposits such as its Culberson mine in western Texas, which Pennzoil eventually sold to Freeport. Texasgulf operated the most prolific sulfur mine in Texas, on Boling dome, extracting 82 Mt of sulfur during more than 60 years of production. The mine closed in 1993.

The United States remains the world's foremost producer and consumer of sulfur and sulfuric acid, with production from recovered and by-product sources. The United States is a net importer of sulfur, however, with most of its imports coming from Canada and Mexico. Canada, the second largest producer, is the world's leading exporter. Other countries that produce 1 Mt or more of sulfur in all forms are Chile, China, France, Germany, India, Iran, Japan, Kazakhstan, Republic of Korea, Mexico, Poland, Russia, Saudi Arabia, and United Arab Emirates (see Table 1).

Poland is the only producer of Frasch sulfur, although production has decreased to only about 750,000 t from one mine; it once produced nearly 5 Mtpy from three mines. Frasch production from the Mishraq deposit near Mosul in the Kurdish north of Iraq could resume when conditions there stabilize; Poland's Frasch producer has shown interest in operating the mine but is waiting until circumstances are more favorable. Iraq's status as a major exporter was negatively affected by the United Nations' trade embargo that was enacted as a result of its invasion of Kuwait in 1990 and was lifted only after the start of the second Gulf War in 2003. China is the only major producer that obtains the majority of its sulfur production from pyrites.

GEOLOGY OF NATIVE SULFUR DEPOSITS

Mineralogy and Classification of Deposits

Elemental sulfur occurs naturally by replacement reactions with anhydrite and gypsum in salt-dome cap rocks and bedded evaporites. It is also common in volcanic environments and associated with thermal springs.

Native sulfur is readily oxidized, particularly in the presence of sulfur-oxidizing bacteria, and so is somewhat ephemeral in nature. Surface exposures are relatively rare and are generally restricted to regions of ongoing or very recent mineralization. Most known sulfur deposits are thought to be Tertiary in age or younger, but some fossil deposits (from which the sulfur has been removed) may be older.

The element sulfur occurs as sulfate (anhydrite and gypsum) throughout the world, and in sulfides, both ferrous and nonferrous. All of these occurrences of sulfur are used locally as a source of elemental sulfur and sulfuric acid. Sulfur is present in organic compounds and as hydrogen sulfide in petroleum and natural gas, and in coal, tar sands, and oil shale.

The atomic weight of sulfur is 32.064, and it has an atomic number of 16. Sulfur has four oxidation states (+6, +4, 0, and -2), of which the S^{-2} sulfide ion and the S^{+6} sulfate cation are the most important in nature.

There are four stable isotopes of sulfur— ^{32}S , ^{33}S , ^{34}S , and ^{36}S —that respectively are 95.02%, 0.75%, 4.21%, and 0.02% of the total terrestrial sulfur. The isotopic composition of sulfur is expressed in terms of $\delta^{34}S$ (Faure 1977). The most important cause for variation in the isotopic composition of sulfur in nature is fractionation by sulfate-reducing bacteria. These bacteria split oxygen from sulfate ions and excrete hydrogen sulfide that is enriched in ^{32}S relative to the sulfate. The extent of the fractionation is variable and depends on the rate of reduction, the temperature, the nature and availability of the food supply, and the size of the sulfate reservoir. Native sulfur from salt-dome cap rock and bedded evaporites (as described in the following text) is enriched in ^{32}S , and the residual anhydrite and gypsum and associated sulfate minerals such as barite are enriched in ^{34}S , lending evidence to the origin of sulfur in these environments by sulfate-reducing bacteria (Thode 1972).

Native sulfur is polymorphous; although it commonly occurs in the orthorhombic or alpha (α) sulfur form, it is also known in two monoclinic forms, beta (β) sulfur and gamma (γ) sulfur. The monoclinic forms are unstable at normal surface temperatures and readily convert to the orthorhombic form. Orthorhombic sulfur, when heated to 95.5°C, changes to monoclinic crystals. Natural monoclinic sulfur is rare, but is known from several sites, including Moravia, in the Czech Republic, where it has been given the name of rosickyite (Ford 1949). Native sulfur also occurs in an amorphous state.

Native sulfur crystals are commonly dipyramidal and sometimes thick tabular on c(001) or sphenoidal. Sulfur also occurs in irregular masses, in reniform shapes, as incrustations and earthy masses, and in stalactitic and stalagmitic forms. Cleavage is imperfect, and fracture is conchoidal to uneven. Native sulfur is brittle to imperfectly sectile, has a Mohs hardness of 1.5 to 2.5, and has a resinous luster. Sulfur has a specific gravity of 2.05 to 2.09. The average weight of orthorhombic sulfur is 2.07 g/mL, the average weight of monoclinic sulfur is 1.96 g/mL, and the average weight of amorphous sulfur is 1.92 g/mL (Ellison 1971). The color of sulfur varies from bright yellow to honey yellow, yellowish brown, greenish, or reddish to yellowish gray. The color depends on the temperature and discoloring impurities such as hydrocarbons and clay.

Sulfur is a nonconductor of electricity and a poor conductor of heat. Orthorhombic sulfur melts at 112.8°C, monoclinic sulfur at 119.2°C, and amorphous sulfur at 120.0°C. Molten sulfur is fairly mobile near the melting point, but its viscosity increases with increasing temperature to 188°C, and then decreases to sulfur's boiling point at 444.6°C. The specific gravity of molten sulfur is 1.79 at 132°C, and the flash point (modified Cleveland open cup) is 168.3° to 187.3°C.

Sulfur is insoluble in water and is nonhygroscopic but is soluble in benzene, ether, toluene, alcohol, and carbon disulfide. It is unaffected by most acids. Sulfur is readily ignited in air, burning at 270°C with a blue flame and evolution of sulfur dioxide. Corrosivity is nil for dry sulfur with slow generation of sulfuric acid when wet. Vapor pressure is less than 0.1 mm Hg (mercury) at 20°C.

Rucknick, Wimberly, and Edwards (1979) classify native sulfur deposits according to genesis in the following fashion:

- I. Biogenic deposits
 - A. Bioepigenetic
 - 1. Cap rock
 - 2. Stratabound
 - B. Biosynthetic
- II. Volcanic deposits
- III. Oxidative deposits
- IV. Thermogenic accumulations

The biogenic deposits listed include all types of mineralization thought to originate through the actions of sulfate-reducing bacteria. The bioepigenetic deposits are the most economically significant and include deposits in salt-dome cap rocks (cap rock above) and replacement deposits in bedded gypsum and anhydrite (stratabound above; stratiform is discussed in the following text). The biosynthetic deposits include small occurrences of native sulfur in modern marine or lacustrine sediments generated by bacterial reduction of sulfate. None of the significant sulfur occurrences in the world is known to be biosynthetic.

Native sulfur is common in volcanic terranes, generally as vein and fracture fillings, and is associated with thermal springs. Volcanic occurrences are generally small, but a few have been mined and are locally important. The oxidative classification of Rucknick, Wimberly, and Edwards (1979) refers to widespread, but generally small, occurrences of sulfur formed at the surface or at depth where hydrogen sulfide (regardless of origin) is oxidized. This class of deposit is discussed in more detail in the section on Stratiform Deposits in this chapter where two oxidative deposits are described.

Native sulfur is also known to originate from high-temperature and high-pressure reactions in deep strata, here termed *thermogenic accumulations*. This type of deposit occurs in association with sour natural gas and is discussed in the section on Recovered Elemental Sulfur in this chapter.

Salt Domes

Salt domes, pillows, and anticlines are common in evaporite basins throughout the world. Salt domes host sulfur mineralization at numerous widespread sites, including Tunisia, the Canadian Arctic, and the Gulf Coast region of the United States and Mexico (Figure 1), but only those salt domes in the Gulf Coast are currently known to host economic sulfur deposits. Salt domes are also important traps for oil and gas accumulations, and the presence of hydrocarbons is essential for the development of native sulfur.

Numerous references discuss the origins of salt domes and cap rock, including previous editions of this volume. Additional overviews of salt domes and pertinent Gulf Coast geology can be found in works by Ellison (1971), Halbouty (1979), Seni (1986), Lerche and O'Brien (1987), Warren (1989), Kyle and Posey (1991), and Salas (1991), among others. Many recent papers present data collected as part of the efforts to evaluate salt domes for the storage of radioactive waste, and data pertaining to fluid migration, cap rock development, and metallic sulfide occurrences.

Salt domes are generally described as diapirs of halite that have intruded younger strata in response to early differential loading and subsequent density inversion. It is misleading, however, to believe that salt is capable of intruding many kilometers of strata. Diapirs begin forming early in the sequence of burial, probably as a response to differential loading, and pass to a stage of diapirism as

overlying strata are loaded on the salt bed in thicknesses greatest where the salt is thinning and migrating toward the diapir (Trusheim 1960; Jackson and Talbot 1986; Posey and Kyle 1988). The top of the salt plug maintains a more or less constant elevation relative to the sediment–water interface, although the buoyancy of the salt and continued upward movement may cause minor faulting and deformation in strata above, and the salt may breach the surface.

In the Gulf Coast, the salt that forms the domes has its source in the Jurassic Louann Formation, a thick deposit of halite thousands of meters below the surface. The Louann halite is relatively pure but contains about 5% in-soluble material, mostly anhydrite crystals with small amounts of dolomite, calcite, and quartz, and traces of limonite, barite, and other minerals.

Subsequent sedimentation on the top of the halite deformed the salt and initiated movement, and was eventually directed to distinct salt plugs that grew in response to continued loading. Late in the history of each salt diapir, the top of the salt plug dissolved through the actions of migrating fresh waters. As salt movement continued upward, the halite at the top was removed and the anhydrite residue accumulated, eventually becoming compacted and cemented. Further dissolution and residue underplating resulted in the formation of a banded anhydrite cap rock that is younger downward. The salt dissolution at the upper surface of the salt stock is relatively flat. The location of active dissolution probably migrates across the salt dome with time, and may be only locally apparent. Only those salt domes that penetrate to within about 2 km of the surface exhibit anhydrite cap rock (Halbouty 1979).

The upper (or outermost) portions of the anhydrite cap rock are commonly replaced by calcite cap rock. Figure 2 is a schematic cross section of a typical salt dome. The calcite cap rock is roughly divisible into two parts: an upper variegated calcite cap and a lower banded calcite cap (Kyle and Posey 1991), both of which may be intensely brecciated and veined with crystalline calcite. The calcite cap is separated from the anhydrite by a transitional zone of gypsum. The underlying anhydrite may be locally absent, particularly at the edges of the dome, if calcite replacement has been complete.

Native sulfur may be found throughout the cap rock and adjacent supercap strata in minor amounts, but it is generally concentrated in the lower portion of the calcite cap. The upper portion of the calcite cap is often barren of sulfur, possibly because of non-deposition or subsequent oxidation. The thickest accumulations of calcite cap, and also of native sulfur, are commonly on the basinward sides of the salt domes, which in the U.S. Gulf Coast is predominantly to the south.

Celestite and barite locally accompany the sulfur as minor accessory minerals. Several recent studies also documented the occurrence of Mississippi Valley type metallic sulfides in both calcite and anhydrite cap rock. Documented sulfide minerals include pyrite, marcasite, pyrrhotite, hauerite, alabandite, sphalerite, galena, chalcopyrite, and acanthite (Price, Kyle, and Wessel 1983; Kyle and Price 1986). Uranium minerals are also found in supercap strata adjacent to salt domes, and realgar has been noted associated with silver values at one dome (G. Wessel, unpublished data 1991).

The origin of sulfur deposits in salt-dome cap rock (and in replacements in bedded evaporites, described as follows) is now widely accepted to be associated with the actions of sulfate-reducing bacteria in the presence of a sulfate source (anhydrite and gypsum) and hydrocarbons. At relatively shallow depths (generally less than 750 m, but locally deeper) and at temperatures below about 60°C, sulfate-reducing bacteria can thrive in the subsurface given an adequate energy source. Sulfate-reducing bacteria are anaerobic, but they are ubiquitous in nature and exist (and probably thrive) with aerobic bacteria in microenvironments.

Figure 1. Sulfur-producing domes in the Gulf Coast region of the United States and Mexico

The origin of the sulfur deposits is complex and depends on several parameters. The host anhydrite must be relatively near the surface and exposed to migrating meteoric waters, so that the anhydrite is hydrated to gypsum and put into solution. Into this system, petroleum or natural gas is introduced from depth, generally along faults and joints or permeable strata. Sulfate-reducing and other bacteria introduced with the meteoric water oxidize the hydrocarbons and reduce the sulfate to hydrogen sulfide, represented by the following reaction (greatly simplified):

The hydrogen sulfide is oxidized to elemental sulfur with molecular oxygen, presumably present in the groundwater, represented by

Hydrogen sulfide may also be oxidized to sulfur by ferric iron, polysulfide disproportionation, or microbially by colorless and col-

ored sulfur-oxidizing bacteria (Machel 1992). The oxidation of hydrogen sulfide by excess sulfate ions has also been suggested as a mechanism for producing native sulfur (Davis and Kirkland 1979; Ruckmick, Wimberly, and Edwards 1979). In more oxidizing environments, hydrogen sulfide may be oxidized to valences higher than zero and no elemental sulfur may be formed.

These reactions basically represent only the end products of sulfate reduction and sulfur deposition. Numerous intermediate reactions have been omitted for clarity but are important to understanding the nature of sulfur generation. Regardless of the mechanism of oxidation of the hydrogen sulfide, it appears that the confinement of the hydrogen sulfide to a restricted area where the native sulfur may be deposited and preserved is critical to the generation of a significant sulfur deposit. Dissipation of hydrogen sulfide to the atmosphere or elsewhere will prevent the deposition of economic quantities of sulfur. Similarly, subsequent oxidation of sulfur mineralization, especially from the actions of sulfur-oxidizing bacteria such as *Thiobacillus* sp., may leave calcite replacement bodies barren of native sulfur. Overlying impermeable strata such

Adapted from Kyle and Posey 1991.

Figure 2. Schematic cross section of a salt-dome cap rock showing an idealized sequence of cap-rock lithologies

as shales are generally credited with providing a barrier to hydrogen sulfide migration and later oxidation.

One particular species of sulfate-reducing bacteria, *Desulfovibrio desulfuricans*, is commonly credited with being the most significant contributor to sulfur mineralization, but several species of *Desulfovibrio* are probably involved, as are species of *Clostridium*, *Desulfotomaculum*, and possibly others. These sulfate-reducing bacteria are strict anaerobes, but they can exist and thrive in microenvironments distributed throughout oxidized strata containing aerobic bacteria. The sulfate-reducing bacteria do not degrade hydrocarbons but use only simple organic substrates such as acetate, lactate, pyruvate, fumarate, and formate (Kuznetsov, Ivanov, and Lyalikova 1963; Ivanov 1968; Postgate 1979; Skyring 1987). Some are thought to oxidize methane, but for hydrocarbons to be considered an energy source, aerobic bacteria must be present to generate appropriate substrates. The process of native sulfur deposition from sulfate reduction most likely involves numerous types of bacteria in a complex and evolving ecosystem.

The amount of hydrocarbons necessary to produce a significant sulfur deposit is fairly large. It is thought that 2 to 4 bbl of oil must be consumed for each ton of sulfur deposited (Ruckmick, Wimberly, and Edwards 1979). The actual amount of hydrocarbons required probably varies depending on local geologic conditions.

Concurrent with the generation of hydrogen sulfide and the deposition of sulfur, calcite in multiple generations (sometimes referred to as biocalcite) is deposited as a replacement of the anhydrite and forms the calcite cap rock. Early generations of calcite may be massive and fine grained; later calcite filling veins and vugs is often finely to coarsely crystalline, white to tan, and commonly petroliferous. Much of the calcite cap rock is a breccia containing clasts of wall rock and earlier generations of calcite and

associated minerals. The calcite breccia may be barren of sulfur because of nondeposition, later oxidation, and removal, or perhaps because of remobilization and nearby reprecipitation as described by Nieć (1992).

The role of sulfate-reducing bacteria in the formation of sulfur deposits is supported by isotope studies of both sulfur and carbon. Sulfate-reducing bacteria fractionate the sulfur isotopes and selectively concentrate the light isotope. The sulfur is enriched in ^{32}S , and the remaining sulfate is enriched in ^{34}S . The calcite cap rock is isotopically similar to the carbon in associated crude oil and significantly enriched in ^{13}C with respect to sedimentary limestone (Feely and Kulp 1957; Faure 1977).

Currently 167 onshore salt domes and 180 offshore domes are known in the Gulf Coast province of Texas (excluding south Texas) and Louisiana (G. Eager and B. Salisbury, unpublished data, 1991). Of the 167 onshore domes, 90 are shallow enough to be prospective for sulfur, and 24 of these domes produced sulfur (included in Table 3); 12 produced more than 5 Mt, 5 produced more than 10 Mt, and 3 produced more than 20 Mt. Mexico was also a significant producer of salt dome-hosted sulfur, but published data on Mexican production and geology are not extensive (Salas 1991). Two of the most important salt domes in the Gulf Coast, Boling dome and Main Pass, are described in the following sections.

Boling Dome

Boling dome is located in Wharton County, Texas, about 100 km southwest of Houston. Discovered in 1922, Boling operated from 1928 to 1993. Operated by Texasgulf Inc., Boling produced more than 82 Mt of sulfur from more than 8,000 wells (Samuelson 1986, 1992; Seni and Kyle 1986, 1987). When the mine closed, sulfur production was at a rate of about 361 tpd, much less than the peak production in 1948 of 8,510 tpd. A cogeneration plant, opened in 1985, generated electricity that was marketed to a local utility. The cogeneration plant kept Boling dome profitable longer than would have otherwise been possible.

Boling dome is the largest salt dome in Texas with an area of 38 km² at the -1,219 m elevation contour. The minimum depth to cap rock is 117 m, and the margins of the cap rock plunge steeply below a depth of 1,524 m.

The cap rock is divisible into three zones: an upper barren calcite zone, a middle calcite/sulfur zone, and a lower anhydrite zone. The transitional gypsum zone, present at other domes, is poorly developed at Boling. The calcite cap rock is composed of light- to dark-gray, fine- to medium-grained calcite that has been brecciated and veined with crystal line calcite. Rhythmically banded calcite, common at other domes, is rare at Boling except near the base of the calcite cap rock. The anhydrite cap rock is dense, dark gray, and composed of interlocking euhedral anhydrite grains cemented by anhydrite. Uncemented anhydrite sands are locally present at the contact with the underlying salt. The top of the salt diapir is relatively flat (Figure 3).

Relatively large amounts of detrital material are incorporated within the cap rock. Lenses of calcitic sandstone and shale, transported to the surface with the salt, are present in both the calcite and anhydrite cap rock, and locally hamper mining operations.

The main sulfur deposit was within the calcite/sulfur zone in the southeastern third of the dome (Figure 4). The richest areas of sulfur mineralization roughly corresponded to the thickest calcite cap rock, which ranges from 0 m to more than 122 m thick. Some wells in the thickest calcite intersected sulfur mineralization averaging 20% sulfur by volume for the entire 122-m interval.

Accessory minerals include barite, pyrite, hauserite, sphalerite, and galena. The barite occurs as filled cavities and as massive

Table 3. Production of Frasch sulfur in the United States and Mexico by mine and company, 1894 through 2000

bodies in the upper part of the calcite cap. The sulfide minerals are concentrated along the east flank of the dome but are not present in quantities of economic interest.

Main Pass

The Main Pass deposit, located in Main Pass Block 299 in U.S. federal waters in the Gulf of Mexico, about 27 km east of Venice, Louisiana, was discovered in 1988 by a joint-venture effort of Freeport-McMoRan Inc., IMC Fertilizer Inc., and Felmont Oil Corp. (which later became Homestake Sulphur Co.). The deposit contained proven sulfur reserves of 68 Mt. The Main Pass deposit is situated in about 63 m of water (Anon. 1991a; Ackerman 1992; Edwards et al. 1992).

Before exploration for sulfur, Chevron discovered oil and gas in strata flanking the salt dome. Freeport's sulfur drilling in 1988 intersected oil and gas reserves within the cap rock and overlying

strata. Freeport purchased Chevron's hydrocarbon reserves and consolidated hydrocarbon and sulfur interests under the Main Pass Joint Venture, which produced sulfur and hydrocarbons. Recoverable oil and gas reserves were 39.4 million bbl and 0.2 Gm³, respectively. The stacked sulfur/oil/gas deposits presented challenging engineering problems for the development staff.

The Main Pass 299 salt dome is roughly circular in plan (Figure 5) with an approximate diameter of 3,000 m at the 900-m subsea contour (Ackerman 1992; Edwards et al. 1992). The top of the dome (about 400 m below sea level) is relatively flat. Cap rock extends over about 680 ha and consists of calcite and anhydrite. Total cap-rock thickness varies from about 40 to 160 m. Sulfur-bearing cap rock up to 70 m thick was intercepted in the exploration program.

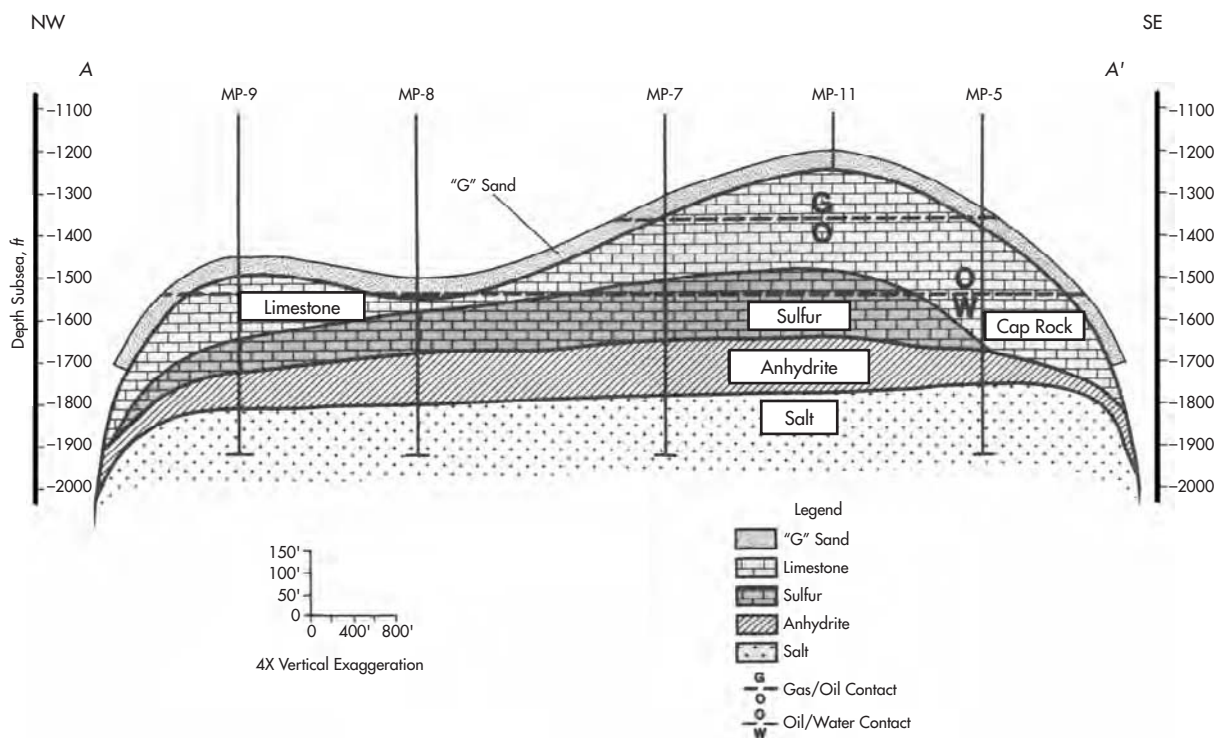

Plans for the mine complex consisted of 15 offshore sulfur mining platforms and related facilities. Production began in 1992 and reached full production in 1993. Production was expected to reach 2 Mtpy over a mine life of 30 years, but developments in the sulfur industry and technical problems forced the closure of Main Pass mine in 2000.

Stratiform Deposits

Stratiform deposits of native sulfur associated with bedded anhydrite and gypsum are relatively common in oil-producing evaporite basins throughout the world, but large deposits suitable for mining are few. Significant stratiform sulfur deposits have been mined in Iraq, Italy, Poland, Russia, western Texas, and Ukraine. Similar occurrences are known in many countries, including Argentina, Angola, Canada, China, Egypt, England, Greece, Iran, Israel, northern Mexico, Romania, Spain, Syria, Turkey, and numerous others. Several deposits that were important operations are described here.

The origin of the stratiform deposits is very similar to that of the salt dome-hosted deposits described previously. Shallow anhydrite or gypsum beds are replaced by biopigenetic calcite and sulfur through the actions of sulfate-reducing bacteria in the presence of oil and migrating meteoric water.

Many of the stratiform deposits are in arid regions where shallow evaporites are more likely to be preserved and are commonly proximal to a major river or other recognized source of meteoric

Figure 5. Cross-section A-A', Main Pass mine, offshore Louisiana (depths shown in feet from sea level)

water. The deposits are usually at the edges of the evaporite basins and are within or adjacent to structures (such as drape folds, anticlines, and faults) that have focused hydrocarbon migration or surface water channeling and evaporite dissolution. As described here, these deposits are difficult exploration targets and are often found by accident during the drilling of oil wells.

Western Texas

Stratiform sulfur deposits are widespread in the Permian Basin of western Texas. Sulfur was the most recently produced from Pennzoil's Culberson mine and also was produced in the past from several smaller deposits. The Permian Basin was the site of intense exploration, most notably in the late 1960s. There are two known sulfur districts in western Texas: the Ft. Stockton District and the Rustler Springs District. The Ft. Stockton District is located on the Central Basin platform that separates the Midland and Delaware basins (Figure 6). The Rustler Springs District and the Culberson mine are located in the Delaware basin portion of the Permian Basin. Sulfur in the Ft. Stockton District occurs with calcite and replaces anhydrite of the Permian Salado, Tansill, and Yates formations. The host formations, as well as formations above and below, drape over the Pennsylvanian-Permian Central basin platform and define a northwest-trending anticline locally termed the Heiner anticline (Figure 7). Structural highs along the axis of the Heiner anticline served as foci for hydrocarbon entrapment and subsequent sites of sulfate reduction and sulfur mineralization (Zimmerman and Thomas 1969; Ellison 1971; McNeal and Hemenway 1972; Hentz, Price, and Gutierrez 1989).

Native sulfur was first noted in the Ft. Stockton District in an oil well drilled in about 1900 (Adkins 1927). Subsequent oil drilling noted other occurrences of sulfur, but it was not until the exploration

Figure 7. Cross section showing stratigraphic distribution of sulfur at Ft. Stockton mine, Pecos County, Texas

surge of the mid-1960s that the Ft. Stockton deposit was discovered. The majority of the district is covered by Quaternary alluvium, and the sulfur mineralization is not exposed at the surface.

Production from the Ft. Stockton District has been limited to three small Frasch mines: Duval's (Pennzoil's) Heiner mine, Sinclair's (Atlantic Richfield's) Ft. Stockton mine, and Texasgulf's Comanche Creek mine. The Comanche Creek deposit is thought to have been the largest with 7.6 Mt of original in-place sulfur, but none of the deposits produced more than 2.0 Mt.

The Rustler Springs District contains numerous small sulfur deposits, and one very large deposit that produced Frasch sulfur until 1999—Pennzoil's Culberson mine. The Culberson mine had an operating capacity of 2.5 Mtpy, but the production rate toward the end of operation was as much lower (Crawford 1990). About 45 Mt of sulfur were produced from the mine. Other production from the Rustler Springs District was limited to the Phillips Ranch deposit, from which 86,360 t were produced from 1980 to 1982. Addvest Minerals built another Frasch operation at the Phillips Ranch site, but never started production because economic conditions were never favorable (Guilinger and Nestlerode 1992).

Mineralization at the Culberson mine is hosted by bedded anhydrite and gypsum in the Ochoan Castile, Salado, and Rustler formations, but most of the ore is within the Salado Formation (Smith 1980; Mussey and Tyree 1985; Hentz, Price, and Gutierrez

1989; Crawford 1990; Wallace and Crawford 1992). The sulfur occurs with calcite and accessory barite and celestite in three general modes (Crawford 1990): (1) as microcrystalline disseminations in gray diagenetic (replacement) limestone or cave-fill breccias, (2) as orthorhombic crystals lining cavernous voids in the replacement limestone, and (3) as coarsely crystalline crusts or agglomerates that nearly fill all voids in the limestone. The diagenetic limestone (calcite) is a product of biogenic replacement of anhydrite and gypsum solution collapse breccias, and original breccia textures are commonly preserved. Similarly, calcite and sulfur locally replace and preserve varves in the Castile evaporite. The ores commonly contain up to 30 wt % sulfur and average about 25% porosity.

The Culberson ore body is elliptical and extends from 100 to 720 m below the surface. The ores are intimately associated with dissolution collapse and cave-fill breccias (Figure 8) that preferentially occur along selected horizons in the Salado Formation (Miller 1992; Wallace and Crawford 1992). The collapse and cave breccias presumably channeled both hydrocarbons and oxygenated meteoric water, and led to the reduction and replacement of evaporite-bearing breccia clasts and adjacent evaporitic strata. The dissolution collapse and cave breccias appear to be localized along notheast-trending Tertiary normal faults and joints. Rarely visible at the surface, such fractures can be inferred from the linear distribution of collapse sinks, minor offsets indicated by oil-well data and sulfur-related

Figure 8. Cross section A-A', Culberson mine, Culberson County, Texas

alteration features. The presence of a residual silty clay cap over the Culberson deposit appears to have been critical to the preservation of hydrogen sulfide and to the generation and preservation of native sulfur (Figure 8).

The presence of sulfur in the Rustler Springs area has been known since 1854. Numerous surface occurrences of sulfur and erosional remnants of bioepigenetic calcite (Kirkland and Evans 1976) are known, and there were several attempts beginning in the early 1890s to mine surface ores (Porch 1917; Evans 1946). Duval Corporation discovered the Culberson mine in 1967 near the site of some old surface works.

Poland

Native sulfur deposits in Poland occur in Upper Miocene strata on the northern (platform) border of the Carpathian foredeep (Figure 9). Sulfur occurs in bioepigenetic calcite replacements of a gypsum unit of Middle Badenian age and is accompanied by barite and celestite. The sulfur deposits are located on uplifted blocks near the northern margin of the Carpathian foredeep at depths from a few meters to about 360 m (Pawlowski, Pawlowska, and Kubica 1979; Anon. 1988, 1990a; Preisner 1991; Nieć 1992).

The sulfur-bearing rocks vary in thickness from a few meters to more than 40 m, and they are subhorizontal. The host strata in nearly the entire region are covered by Quaternary deposits of variable thickness.

The sulfur content of the ore is quite variable and ranges from a few percent up to more than 50% in selected samples. Rocks containing less than 5% sulfur are considered barren. The average sulfur content of individual deposits varies from 22% to 33%. Ore textures commonly mimic textures in the original gypsum.

Small surface deposits of native sulfur have been exploited on a limited scale for hundreds of years. The earliest documented sulfur mining in Poland occurred in 1415, but it was not until 1953 that exploration efforts resulted in a discovery of sulfur-bearing limestone in the subsurface near Tarnobrzeg, which became the center of sulfur mining.

There were two main sulfur-producing areas in Poland: the Staszow-Tarnobrzeg region containing four deposits and the Lubaczow Area where one deposit is dissected by the Polish-Ukrainian border. The regional trend of sulfur mineralization follows the northern margin of the Carpathian foredeep into Ukraine, where sulfur was mined at several deposits using both Frasch and open-pit methods. Westward from Staszow-Tarnobrzeg, only small sulfur deposits have been found, some of which were mined before 1921.

The known Polish sulfur deposits together contain approximately 600 Mt of demonstrated sulfur reserves and about 500 Mt of inferred and hypothetical resources (Nieć 1992). Open-pit mining was begun in 1956 at the Piaseczno mine, and Frasch mining modified to fit the unconfined ores of the Polish deposits (the thermohydrodynamic or hydrodynamic method) has been successfully applied since 1966 (Anon. 1986b). One hydrodynamic mine remains in production. At its peak, total annual sulfur production reached more than 5 Mtpy, but the annual capacity at the last active mine is only 800 ktpy. The total recovery from the sulfur deposits varied between 40% and 70%.

Iraq

Sulfur deposits in Iraq are found in the folded portion of the Mesopotamian depression that separates the nappes and the Zagros

Adapted from Barker, Cochran, and Semrad 1979.

Figure 11. Cross section A–A' and B–B', Mishraq deposit, northern Iraq (locations of cross sections shown in Figure 10)

and molten sulfur were observed to be pouring out of the bluff and into the Tigris River, causing severe contamination (Babbitt 1991). Fluids also leaked into adjacent barren structures as far as 3 km away. This indicated excessive costs from fluid loss and overheating of the host rock.

The inclusion of carbon, hydrocarbons, and ash in Mishraq sulfur was a problem in marketing Iraqi Frasch sulfur. Early filtering systems were inadequate and routinely resulted in losses of up to 50%. Efforts by Freeport under contract to MSSE to construct a filtering plant were halted by Iraq's 1990 invasion of Kuwait. The resulting war led to the destruction of some recovered sulfur plants, but there were no reports of significant damage to the Mishraq facility.

During Iraq's war with Iran in the 1980s, production at Mishraq varied widely. In 1981, total Iraqi sulfur production (of which about 80% comes from Mishraq) was 145 kt; in 1987, it was 850 kt (Anon. 1989). Before the invasion of Kuwait, Iraq was producing about 1.8 Mtpy, with Mishraq producing about 1.4 Mtpy. MSSE had previously announced that production at Mishraq would expand to 2.0 Mtpy by 1991, but continuing political and economic instability adversely affected production through 2004. If the country achieves stability, a large increase in sulfur production could occur, possibly with the assistance of the Polish sulfur producers.

Oxidative Deposits

Ruckmick, Wimberly, and Edwards (1979) also included a category of deposits that they termed oxidative. In the strictest sense, almost all native sulfur deposits are oxidative in that they are formed from the oxidation of hydrogen sulfide, but this category properly includes only those deposits not associated with volcanic or biogenic sources of sulfur. They probably are formed as a result of the

oxidation of hydrogen sulfide from a remote source, resulting in native sulfur deposition in existing voids in porous host rock. The hydrogen sulfide may originate in high-temperature diagenetic settings, such as those associated with thermal maturation of crude oil and thermochemical sulfate reduction (Machel 1992), but the source of the hydrogen sulfide is commonly difficult to identify. Oxidative deposits are widespread, but they are generally small and are not currently used as a source of sulfur.

Oxidative deposits of native sulfur have been described in Lechuguilla Cave, located in the Capitan reef at the northern margin of the Delaware Basin (near Carlsbad Caverns, northeastern New Mexico), as well as in western Texas. At Lechuguilla Cave, hydrogen sulfide dissolved in basinal brines was oxidized to native sulfur and is intimately associated with speleogenesis there and at Carlsbad Caverns (Spirakis and Cunningham 1992).

Numerous occurrences of native sulfur in porous carbonate strata of the San Andres Formation, Permian Basin, western Texas, are also probably oxidative deposits of this type. One such deposit, the Mustang Draw occurrence in Glasscock County, Texas, was a site of exploration activity from 1987 to 1990. A resource of 7.4 Mt of sulfur was identified in rock that locally contains 6.5% sulfur by volume (Ruckmick et al. 1992). A similar occurrence in the Permian Clearfork Formation south of Mustang Draw was the site of an unsuccessful pilot Frasch test in 1968 (Zimmerman and Thomas 1969; Ellison 1971).

Volcanic Deposits

Sulfur of volcanic origin is probably the most widely distributed of native sulfur deposits. Deposits of this type are known in nearly all volcanic regions of the world, particularly in the Pacific Rim region: deposits are present in western North and South America,

Central America, the Kamchatka Peninsula, the Kurile Islands, Japan, the Philippines, Indonesia, Taiwan, and New Zealand. Deposits are also present in volcanic regions in western Turkey, Greece, Italy, and elsewhere.

Volcanic sulfur deposits can be subdivided into four types by mode of emplacement (Barker 1983; Níeć 1986a):

1. Impregnation and replacement deposits, usually formed by the actions of hot-acid springs that are rich in sulfurous gases, often in tuffs and volcanic breccias, with sulfur in irregular or lens-shaped or ebbodies aligned along fracture zones; accompanied by sulfides and alteration (aunitization, argillization, silicification) that locally completely replaces the host rock; economically the most important of the volcanic deposits
2. Sublimation deposits, formed by gaseous or fumarolic activity near volcanic craters, where sulfur coats fractures and cavities near the surface in small deposits that are locally mined
3. Sedimentary deposits, formed by precipitation of sulfur in hot crater lakes
4. Sulfur flows, small-flow deposits that probably originated from older deposits that were remelted; of local importance only

Volcanic sulfur deposits are usually found in tuffs, lava flows, and other volcanic rocks but are also found in sedimentary, intrusive, and other rock types in volcanic regions.

Volcanic deposits have been mined in the past in many areas, but significant production of volcanic sulfur has been limited to Japan, Turkey, Mexico, Italy, and the Andean countries of South America. Mining methods used include standard underground and surface mining methods as described here.

Mined volcanic sulfur dominated Japanese production until the mid-1960s, when recovered sulfur challenged its importance (Anon. 1985b). The mining of volcanic ores in Japan ceased completely in the mid-1970s. Sulfur deposits in a highly altered rhyolite dike near Keciöorlu in southwest Turkey supplied much of Turkey's domestic demand in the past. In the United States, several deposits have been mined to supply local needs, including the Leviathan deposit in Alpine County, California, which was mined from 1953 to 1962 to supply sulfuric acid for Anaconda's Yerington, Nevada, copper operation. More recently, numerous projects have been initiated to recover sulfur from volcanic ores, including sites in South America (Anon. 1987a), Romania (Fodor et al. 1989), the Philippines (Anon. 1986a), Utah (Slim 1986), and California (Ward 1992).

In comparison to biopigenetic deposits, volcanic sulfur deposits are generally small. Few contain more than 10 Mt of reserves, but some (such as the Matsou deposit in Japan) are significantly larger. Volcanic deposits are also at a disadvantage because they are sometimes located far from markets and economical transportation. In addition, volcanic sulfur is commonly impure and contains elements (such as arsenic, selenium, and tellurium) that make it unsuitable for some applications. Some ores cannot be economically processed using existing technology. Commercial interest in volcanic deposits is high only when premium or protected markets exist.

EXPLORATION TECHNIQUES

Exploration for native sulfur deposits is a difficult task, especially for Frasch-minable deposits. There is often little indication at the surface of subsurface sulfur deposits, and surface exposures of sulfur are rare because of the instability of elemental sulfur (it is readily oxidized to soluble sulfate). Indirect indicators may be all

the geologist has to suggest the presence of sulfur, and subsequent drilling may be necessary to fully test such blind targets.

For biopigenetic deposits, the genetic relationship between hydrocarbons and sulfur dictates that exploration be directed to appropriate host rocks in areas that contain oil or gas. For this reason, sulfur exploration commonly makes extensive use of oil and gas well data, so much so that sulfur exploration is sometimes almost indistinguishable from efforts to locate shallow oil and gas reserves. The sulfur geologist is essentially looking for a potential oil trap adjacent to or within evaporitic strata that has been biodegraded and is now replaced by calcite and sulfur. Exploration drilling for sulfur sometimes intersects oil and gas accumulations, just as oil wells commonly intersect sulfur shows.

Barker, Cochran, and Semrad (1979) and Níeć (1986a) summarized the general conditions necessary for the generation of stratiform sulfur deposits:

1. Thick anhydrite or gypsum beds, generally in the border regions of evaporite basins
2. Proximity to hydrocarbon accumulations in correlative or underlying strata
3. Hydrodynamic communication between sulfates and hydrocarbons, often along joints, faults, solution-derived porosity, or other structural or stratigraphic pathways
4. A stratigraphic or structural trap (anticlines, monoclines, horsts, etc.) to contain the precursors of the sulfur-forming reaction
5. Serial, coincident, or coexisting reducing and oxidizing environments where hydrocarbons are biodegraded and sulfate is reduced and then oxidized to sulfur
6. An overlying barrier to fluid migration capable of containing reaction products and preventing later oxidation of sulfur

Tools useful in locating stratiform deposits are few and locally unreliable. Standard field and photogeologic techniques are commonly used to identify prospective structures and surface alteration. Detailed mapping such as that described by Wessel (1992) is valuable where surface exposures are adequate. Surface occurrences of sulfur or biopigenetic calcite (verified by isotope studies) are most encouraging, as are occurrences of sulfur and biopigenetic calcite in oil and gas well cuttings. Anomalous occurrences of silica and iron staining or bleaching are sometimes considered evidence of leakage of reactants from below. A number of surface geophysical surveys (including gamma ray spectrometer, spontaneous potential, resistivity, induced polarization, and ground and airborne magnetic) are used to locate hydrogen sulfide plumes and alteration halos (Salisbury 1992). Thermal infrared, remote sensing, and seismic data have been locally useful, and some surface geochemical techniques (soil gas, airborne gas spectrometry, etc.) have been tested.

Gravity surveys are routinely used to locate stratiform sulfur deposits because of the void development and brecciation associated with sulfur mineralization. Unaltered anhydrite has a density of about 2.96, and sulfur ore bodies vary in density from 2.00 to 2.40, yielding a potentially measurable negative gravity anomaly. The amount of variation depends on the nature of the sulfur mineralization, void development, depth of mineralization, and numerous unknown stratigraphic and structural variables. Gravity data are best used in combination with other data, but interpretation is always difficult (Schmoker 1979; Salisbury 1992). Actual use has resulted in few exploration successes.

Downhole logs of oil and gas wells are commonly used to establish formation control and identify low-density zones that may

indicate sulfur mineralization. The use of these logs is limited where well density is low or shallow strata are not logged.

Salt domes present perhaps the most straightforward exploration problem. The locations of most salt domes are known in areas such as the Gulf Coast of the United States and Mexico as a result of past oil exploration efforts. In the United States, the onshore domes have been intensely explored, and little potential remains for exploration success. Many offshore domes, however, remain untested for sulfur, and the likelihood of another discovery like the Main Pass remains high. Given that the location of a specific salt dome is known, the prudent sulfur prospector could evaluate its potential based on the depth and thickness of cap rock, the presence (if known) of calcite cap rock, and the presence (if any) of shows of mineralization or alteration in oil wells. Gravity and seismic data can be used to define the shape of the cap rock. Gravity data can also indicate potential ore bodies in the cap rock, but again, the interpretation of gravity data is often difficult. Oil-well shows of sulfur and bioepigenetic calcite are the most commonly used guides to mineralization. Hydrogen sulfide springs may be present at the surface, but they are not reliable indicators of mineralization. Other surface indications and techniques previously described are often not applicable, particularly in the Gulf Coast.

Exploration for volcanic sulfur follows the more conventional style associated with exploration for hydrothermal deposits. Similar to bioepigenetic deposits, some volcanic deposits are discovered by accident during metals exploration (Ward 1992). Exploration for other sources of sulfur, such as pyrites and sour gas, is uncommon because they generally supply sulfur only as a by-product.

For many sulfur deposits, the most successful exploration tool is the drilling rig. Nevertheless, great care must be taken to correctly describe and interpret cuttings, core, and other drilling data. There is no substitute for an observant and skilled field geologist.

MINING AND PROCESSING OF NATIVE SULFUR ORES

Sulfur mining uses three different mining techniques: conventional underground methods, conventional open-pit methods, and the Frasch mining (or underground melting) method. The last method is specific for sulfur owing to the low temperature at which sulfur melts. Most mined sulfur has been obtained through Frasch mining; most of the remaining sulfur has been recovered using surface mining techniques, and very little has been obtained by underground mining methods (Níeć 1986b).

For surface and near-surface sulfur ores, surface mining methods predominate, but conventional underground methods also are used, particularly in steeply dipping volcanic deposits. Techniques used include open pit, tunneling, room-and-pillar, cut-and-fill systems, and various forms of stoping. These methods are generally confined to shallow high-grade ores with no overlying impermeable barrier that might allow use of the less costly Frasch mining technique. Underground mining techniques are seldom used because of relatively high costs and because of technical problems related to the common abundance of subsurface water and hydrogen sulfide. Ore recovered from surface and underground mines is processed to separate the sulfur from the host rocks and associated contaminants by various combinations of melting, distillation, agglomeration, flotation, and solvent extraction (Dale 1981; Fodor et al. 1989).

Herman Frasch, the research and development director for Standard Oil Co. and the founder of the Union Sulphur Co., devised the Frasch mining process. First used in 1894 at the Sulphur Mine dome in Louisiana, the Frasch technique is now used to extract native sulfur from salt domes in the United States and Mexico, and (with local modifications) from stratiform deposits in western Texas, Poland, the former U.S.S.R., and Iraq.

The Frasch process capitalizes on several characteristics of sulfur—the low melting point (about 115°C), its insolubility and immiscibility in water, and a specific gravity of 1.8. Basically, the process involves heating water to about 165°C and pumping the heated water through the deposit. The heat from the water melts the sulfur, which sinks and accumulates in a pool below the hot water. The sulfur is then lifted with air out through nested pipes in the same hole used to inject the water.

Requisites for the economical production of sulfur using the Frasch process are (1) a large sulfur deposit (preferably more than several million tons) hosted in a porous and permeable formation, generally cavernous limestone breccia; (2) impermeable or partly permeable stratigraphic seals bounding the ore body so that it is hydrologically isolated; (3) a large, dependable supply of water; and (4) an inexpensive fuel supply. An attractive deposit would contain more than 10 Mt of recoverable sulfur, average 20% or more of sulfur over an interval of at least 30 m, lie between 65 and 800 m deep, have a uniform porosity of 10% to 15%, and be overlain by an impervious bed (Donner and Wornat 1973). Deposits less attractive than this may still be very profitable, but deposits exhibiting poor characteristics may be mined only in special cases (Níeć 1986b).

Figure 12 shows a typical Frasch well. A single well consists of four concentric pipes varying in diameter. The outer pipe acts as a protective casing and extends to the top of the barren cap rock. The next pipe extends to the bottom of the ore body and carries the flow of hot water, which is forced into the sulfur-bearing formation through perforations at the bottom of the pipe. As sulfur melts, it percolates down through the porous host rock to form a pool of liquid sulfur at the bottom of the well. Of the two inner pipes, the smaller one in the center carries compressed air to foam and lift the sulfur through the larger pipe to the surface, where the air is removed from the sulfur in a separator before shipment via heated pipeline, barge, or railcar to storage, or to a sulfur-forming device to be solidified in various forms. The volume of the compressed air and hence the rate of production are closely monitored so that the production rate equals the sulfur melting rate in order not to deplete the sulfur pool and cause the well to produce water. If the pool is depleted, production is stopped and additional water is injected until the sulfur pool is reestablished (Donner and Wornat 1973; Anon. 1990b). Bleed wells that extract cooled water from the deposit are generally located at the edges of the mining area. Individual sulfur wells usually recover sulfur from an area of less than 2,000 m² and may be operated only 3 to 4 months before exhaustion. Large operations generally have a continual program of drilling to replace wells that become exhausted. On average, about 70% of the sulfur is ultimately recovered.

The philosophy of Frasch mining is to keep the temperature inside the deposit as close as possible to 150°C, at which the viscosity of sulfur is lowest. At temperatures greater than 160°C, the viscosity dramatically increases and sulfur may become unrecoverable.

The costs and availability of water and fuel are often critical to the economical operation of a Frasch mine. A large quantity of water is injected to mine the sulfur, up to 57 m³ or more per ton of sulfur mined, and a dependable supply of water is desirable. Freshwater is generally preferred, but seawater has been used successfully at several sites in the Gulf of Mexico (Barker 1983), including the Main Pass mine (Ackerman 1992; Edwards et al. 1992).

In areas like western Texas where water is scarce, excessive fluid loss was minimized. Water from the bleed wells, a mixture of spent injection water and connate water that was contaminated with corrosive and scale-forming solutes, was locally treated, reheated, and reinjected. This eliminated environmental problems associated with the disposal of contaminated bleed water.

Figure 12. Schematic cutaway view of a typical Frasch well

Fuel-cost increases during the energy crises of the 1970s also led to increased reinjection of spent waters and the development of several new recycling methods (Anon. 1990b) to minimize heat losses. One system developed by Freeport recycled mine water underground by mixing it in place with “new” superheated water. This system reportedly reduced the energy consumption of a well producing over 2 tpd to a third of the original amount. Fuel substitution and cogeneration also circumvented rising energy costs, as at Texasgulf’s Boling dome mine.

In stratiform deposits where the sulfur-bearing rocks are not hydrologically isolated from adjacent strata, fluid loss through underlying or overlying strata can prevent economic sulfur recovery. Such a situation exists in Poland where, in contrast to the salt domes of the Gulf Coast that are at moderate depth and spatially isolated, the sulfur deposits are at shallow depths, are only 10 to 15 m thick, and overlie permeable strata. They are also permeated by meteoric water. For these reasons, the hydrodynamic method (a variation of the Frasch process) was developed and has been used since 1966. The hydrodynamic method was also used in Iraq, and a similar technique was used to exploit the Culberson deposit in western Texas (Anon. 1990b).

The hydrodynamic method uses the same concentric well piping as in the Frasch process, but the wells are arranged in rows along an exploitation front. Because the sulfur-bearing rock cannot retain the heated water under pressure, special measures are used to direct the flow of water underground, including mud injection to seal off areas, judicious blasting to create permeability, and water withdrawal through depression wells placed in advance of the exploitation front. The injected water is thus directed to the depression wells rather than being lost in all directions.

Molten sulfur tends to adhere to the host limestone, leaving about 5% residual sulfur in the ore deposit. For this reason, and because islands of unmelted sulfur remain between production holes, few Frasch operations recover more than about 70% of the sulfur in place, and many sulfur deposits that have been abandoned

yielded considerably less than that (Anon. 1990b). As a result, several secondary and tertiary recovery techniques have been developed, including the Thermofluid technique described by Zakiewicz (1986). Secondary recovery techniques are most popular during times of high sulfur prices.

RECOVERED ELEMENTAL SULFUR

Recovered elemental sulfur as discussed here is largely a nondiscretionary by-product of petroleum refining, natural gas processing, and coking plants. Recovered sulfur is produced primarily to comply with environmental regulations applicable directly to processing facilities or indirectly by restricting the sulfur content of fuels sold or used.

In 2003, involuntary sources of sulfur contributed nearly 97% of the elemental sulfur produced worldwide, a dramatic increase since 1990 when recovered sulfur represented 65% of elemental sulfur production. The combination of recovered elemental sulfur and by-product sulfuric acid was more than 90% of the total world production of sulfur in all forms in 2003, up from 58% in 1990.

The principal sources of recovered sulfur are hydrogen sulfide in sour natural gas and organic sulfur compounds in crude oil. Recovery is mainly in the elemental form, although some is converted directly to sulfuric acid. Smaller quantities of sulfur are recovered from oil sands, oil shale, and coal, although oil sands are increasing in importance in Canada. Of the 24 countries that produced more than 500 ktpy of sulfur in all forms in 2003, recovered elemental sulfur is the dominant sulfur source in 15 of them—Canada, France, Germany, Iran, Italy, Japan, Kazakhstan, Kuwait, Mexico, the Netherlands, Russia, Saudi Arabia, the United Arab Emirates, the United States, and Uzbekistan (Table 1). Table 4 shows salient statistics for the U.S. sulfur industry.

Sour Natural Gas and Crude Oil

The growth in the recovery of sulfur from sour natural gas and crude oil since the mid-1950s has been one of the most significant trends in the sulfur industry. Generally expanding at the expense of Frasch production, recovered sulfur production has steadily increased for reasons independent of sulfur demand. The introduction of stricter environmental controls, combined with increased market demand for lighter petroleum products, a trend toward refining heavier, sourer crudes, and increased use of sour gases led to the availability of greater quantities of recovered sulfur, commonly at a substantially lower price than Frasch sulfur. Recovered sulfur producers usually incur additional transportation costs because many of the production facilities are far from major consumers, but their product is always price competitive. Because it is an involuntary by-product, the cost of production attributed to recovered sulfur is more a question of accounting practices.

Sulfur in oil occurs as organic sulfur compounds such as mercaptans (thiols), alkyl and aryl sulfides and disulfides, thiophenes, and complex condensed aromatic heterocyclic sulfur compounds, which must be converted to hydrogen sulfide before the recovery of sulfur. Sulfur in natural gas is mainly in the form of hydrogen sulfide, which must be removed from the gas at the wellhead because of its toxicity, corrosiveness, and chemical activity. Hydrogen sulfide forms in high-temperature diagenetic settings (such as in deep oil and gas reservoirs) through the thermal maturation of crude oil and through thermochemical sulfate reduction. Thermochemical reduction of sulfate by hydrocarbons is probably responsible for the bulk of the hydrogen sulfide found in this setting (Machel 1992).

Elemental sulfur is also present in high-temperature hydrocarbon reservoirs as a result of oxidation of contained hydrogen sulfide by sulfate and other processes. The elemental sulfur generally

*** Consumption is calculated as shipments minus exports plus imports.

occurs as disseminated droplets of liquid sulfur. Large quantities of sulfur also may be present as polysulfides or dissolved in the hydrocarbon fluids. Lowering of reservoir temperature and pressure (as in a well string) can result in exsolution of elemental sulfur and plugging of rock formations and production equipment. Ruckmick, Wimberly, and Edwards (1979) call such occurrences thermogenic. Hydrogen sulfide originating from thermochemical sulfate reduction may also migrate to near-surface environments and become oxidized to native sulfur. This mechanism may explain some of the enigmatic oxidative occurrences previously discussed.

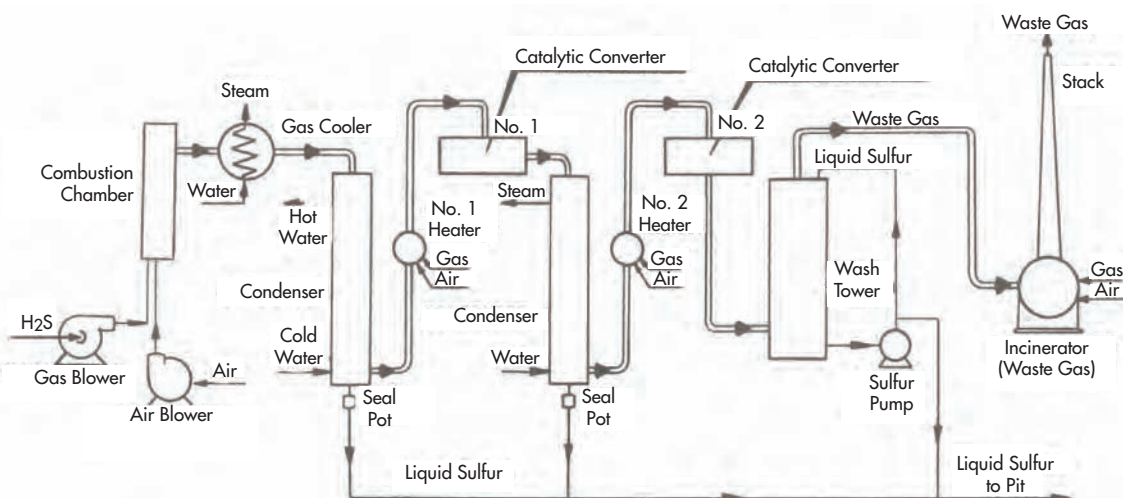

Sulfur in crude oil is recovered during the refining process, and the amount of sulfur recovered depends on the sulfur content of the crude, the amount of crude processed, the refining process, and the products. Refineries in the past were equipped to remove the sulfur only from the lighter refinery products, and much of the sulfur in the crude oil remained in the refinery emission gases or the residual fuel oils and was ultimately emitted to the atmosphere when these oils were burned. Environmental restrictions now limit the quantity of allowable emissions and severely reduced the sulfur content of most finished products from petroleum refineries. The amount of sulfur recovered is increasing because of the increasing

use of heavier and sulfur-rich crudes and more recent requirements to recover most of the sulfur content of the crude oil.

The organic sulfur compounds in crude oil must be removed from the refinery feed and converted to hydrogen sulfide by a hydrogenation process before the sulfur can be recovered. The sulfur in natural gas is already present as hydrogen sulfide, separable from the hydrocarbon gases by a variety of processes (Hyne 1982; Anon. 1987b, 1987c). A process developed by C.F. Claus in Germany in 1883 converts hydrogen sulfide from both sources to elemental sulfur. Over the years, the Claus process has been improved and modified to fit a variety of situations, so that it has become known as the modified Claus process. The basic process is now used in hundreds of sulfur recovery units with different configurations throughout the world, collectively referred to simply as Claus plants. Anon. (1986c) gives an excellent overview of the Claus process in its various forms.

The process was based on the following reaction in which hydrogen sulfide is burned to yield elemental sulfur and water:

Source: Barker 1983.

Figure 13. Generalized flowsheet of a Claus plant for recovery of sulfur from hydrogen sulfide

Only under ideal conditions does this reaction happen exactly as described. Modern Claus reactors incorporate a two-step process that takes advantage of the following reactions:

In the first step of the process, insufficient oxygen is present to convert all the H_2S to SO_2 , thus also causing elemental sulfur and water to be formed. In the second stage, the reaction product SO_2 from the first reactor mixes with additional H_2S , completing the formation of elemental sulfur and water, usually with the aid of a catalyst. The sulfur condenses and is removed in molten form from the reaction vessel and stored until shipping or use onsite (Lefler 2000). Figure 13 shows the Claus process in a generalized flow sheet.

The efficiency of the Claus process for sulfur recovery from gas streams containing H_2S depends on the concentration of the H_2S being treated. The modifications to the process have improved the recovery of sulfur, although not all the sulfur is recovered. Typical sulfur recovery efficiency at Claus plants is 90% to 96% for a two-stage reactor and 95% to 98% for a three-stage reactor. If the depleted process gas is within acceptable limits, it is then incinerated in the final stage of the Claus process to oxidize all the remaining sulfur compounds, and the remainder, or tail gas, is emitted into the atmosphere. Usually, however, the tail gas must undergo further processing to remove as much of the sulfur as technically possible to meet environmental requirements. In the United States, 99.9% recovery efficiency is required at sulfur recovery plants with a capacity of at least 20 tpd. Amine-based tail gas treatment is the most common tail gas process in the United States, where sulfur compounds in the tail gas are converted to H_2S , separated, and recycled to a Claus plant. Other developed countries have similar requirements. Canada requires sulfur recovery of 98.5% at 50-tpd plants and 99% for 2,000-tpd operations. The European Union (EU) mandates 98.5% sulfur recovery. Germany, a member of the EU, has set higher standards of 99.8% for 20- to 50-tpd plants and 99.5% for those with larger than 50-tpd capacity. Japanese operations must recover 99.8% of sulfur; and Taiwan has the highest standard at 99.95% recovery (Connock 1998).

In 2003, 38 companies in the United States produced sulfur at 106 plants in 26 states and the U.S. Virgin Islands. The number of companies producing recovered sulfur has decreased significantly since 1990, primarily owing to consolidation in the energy industry. Most of these plants are small, with 33 reporting annual production exceeding 100 kt. By source, refineries or satellite plants treating refinery gases and three coking plants produced 78.2% of the recovered elemental sulfur. Natural gas treatment plants produced the remainder. The leading U.S. recovered sulfur producers in 2003, all with more than 500 kt of production were, in descending order of production, Exxon Mobil Corp., BP PLC, ChevronTexaco Corp., ConocoPhillips Corp., Shell Oil Co., and CITGO Petroleum Corp. These companies collectively accounted for 68.4% of recovered elemental sulfur production in 2003 (Ober 2004).

Canada is the second largest involuntary producer of sulfur in the world, with a 2003 production of 8.1 Mt, all from oil and gas (Ober 2004). Canada is also the world's largest sulfur exporter. Canada's ability to export most of its production from Vancouver and its willingness to ship large volumes of sulfur contributed to its dominance of the sulfur market.

Most Canadian sulfur production comes from sour natural gas processing plants in the western Canadian sedimentary basin in Alberta, although production in British Columbia is significant also (Anon. 1991a). Occurrences of native sulfur are also known in Alberta, British Columbia, Nova Scotia, and elsewhere, some of which are oxidative deposits (Hollister 1984; Hora and Hamilton 1992).

Recovered sulfur production in Alberta began in 1952 (Anon. 1984a), but sales did not match production until 1979, when adequate transportation and marketing facilities were established. Before 1979, sulfur was stockpiled, reaching a level of more than 21 Mt in 1977 (Schwalm and Doyle 1987). Strong export sales reduced the Canadian stocks to about 3 Mt by 1992, but since then inventories have increased, reaching nearly 15 Mt in 2002 (Ober 1994; Anon. 2002).

Russia is the world's second-largest exporter and the third-largest producer of recovered sulfur, most of which is a by-product of natural gas processing. The Astrakhan gas processing plant is the largest single source of recovered sulfur in the world. Construction

of Astrakhangazprom's first gas processing plant began in 1981 and production started in 1986. The gas is very sour, containing 26% hydrogen sulfide, and is more than 4,000 m deep. Astrakhan produces gasoline, diesel, furnace fuel oil, kerosene, and liquified gas. Sulfur production has increased significantly since 1995 with the completion of subsequent phases of development. In 1995, production at this operation was 1.7 Mt of sulfur. By 2000, production had more than doubled to 3.8 Mt, and future increases may reach 4.5 Mt (Anon. 2001). Orenburg is another sour-gas operation in Russia, with sulfur recovery of about 800,000 tpy.

The Tengiz oil and gas field is the main source of current sulfur production in Kazakhstan. Located on the northeastern shore of the Caspian Sea in western Kazakhstan, Tengiz has been operated by Tengizchevroil (TCO) since 1993. One of the world's largest oil fields, Tengiz contains high-quality oil with 0.49% sulfur and associated natural gas that contains 12.5% hydrogen sulfide (Connell et al. 2000). An expansion plan at Tengiz to nearly double oil production includes the reinjection of sour gas, limiting total recovery of sulfur at the site (Anon. 2003c). Sulfur also is recovered from the Karachaganak gas-condensate field in Kazakhstan near the Russian border. Because it is close to the Russian gas-processing operation in Orenberg, sour gas from Karachaganak is treated at Orenberg. No gas treatment facilities have been installed at the site (Anon. 2001).

In Western Europe, France, Germany, Italy, and the Netherlands are the leading producers of recovered sulfur from natural gas and refineries. Recovered sulfur production in the Middle East is mostly from associated natural gas. Petroleum produced in this region may have high sulfur content, but much of it is exported, and so the sulfur is recovered in other countries. The largest producer is Saudi Arabia, but significant quantities are also recovered in Kuwait, Iran, and the United Arab Emirates. Japan's elemental sulfur production is entirely attributed to oil refining; Mexican production is from a combination of gas processing and oil refining.

Oil Sands

Sulfur is recovered from synthetic crude oil derived from oil sands in Canada. As conventional petroleum production in Canada has declined, oil sands have become a more important source of petroleum for the North American market (Cunningham 2001). The proportion of Canadian petroleum production from oil sands is expected to increase from 9% in 2001 to 21% in 2005 and 30% in 2010 (Pok 2002). Oil sands represent a large source of recovered sulfur, and they offer potential for huge additional quantities in the future. Alberta has huge deposits of oil sands, with estimated reserves of 300 billion bbl of recoverable crude oil that also contain 4% to 5% sulfur as organic sulfur compounds (Stevens 1998). Known for more than 200 years, the Athabasca oil sands in the Ft. McMurray Area of Alberta are a mixture of sand, water, clay, and bitumen (a naturally occurring viscous mixture of heavy hydrocarbons). Because of its complexity, bitumen is difficult or impossible to refine at most oil refineries. It must be upgraded to a light-oil equivalent before further refining, or it must be processed at facilities specifically designed for processing bitumen (Anon. 1999a). During upgrading and refining the oil sands, significant quantities of sulfur must be recovered using processes designed for conventional oil refining.

The Athabasca deposits crop out locally and are visible at the surface and amenable to conventional surface-mining techniques, but most of the oil sands are buried up to depths of 50 m and require in situ mining methods. Three surface mines are in operation at oil sand deposits, and several other operations are producing small quantities of bitumen using an in situ method that injects steam into

the oil sand, separating the water and bitumen from the sand particles. The bitumen is then removed from the deposit, and the sand remains in place. Many additional projects of both types are planned (Anon. 2004d).

Other large deposits of oil sands are known in Venezuela and Colombia. The United States has deposits in California, Kentucky, New Mexico, Utah, and elsewhere, but they are comparatively small. Interest in recovering oil from sands, and consequently sulfur, is highly dependent on the price of crude oil.

Other Sources

More important than oil sands as a potential source of synthetic crude oil (and by-product sulfur) for the United States are its oil shale deposits, particularly those in Colorado, Utah, and Wyoming (Gray et al. 1982). Several companies developed processes to recover oil from shales between 1940 and 1990, primarily in western Colorado, but the relatively high costs of extraction coupled with the problems of disposal of the spent shale have combined to prevent large-scale use of oil shale. As with tar sands, interest in processing oil shale tends to wax and wane with the economic fortunes of the oil industry, although local conditions, such as political isolation or foreign currency restrictions, may spur the development of oil shale resources.

In the United States in 2003, electric utilities and other power producers burned more than 1 Gt of coal with an average sulfur content of 0.94% (Anon. 2004a). Essentially none of the sulfur in coal is recovered before its combustion, although coal-cleaning technologies are capable of removing a substantial portion of the contained sulfides. Pyrite recovered from coal-bearing strata was an important source of sulfur in China, but its importance is declining (Anon. 1985b). Much of the sulfur contained in coal is recovered from coke oven and combustion gases as described in the Sulfur Dioxide Emission Control section of this chapter.

The organic sulfur compounds in coal can be removed only by processes of hydrogenation, liquefaction, or gasification, which change the form of the coal (Gray et al. 1982). Sulfur is produced from coal gasification in the United States, from coal liquefaction in Europe (principally Germany) and in the Republic of South Africa, and from lignite gasification in Spain. Total production from these sources represents a very small portion of global sulfur production.

COMBINED SULFUR

Sulfur is also recovered from sources where it is chemically combined with other elements, principally as a sulfide or sulfate. Such compounds are processed directly to recover the sulfur as sulfuric acid or other forms, and sulfur is recovered from gaseous pollutants arising from the processing of sulfides in metal ores, coal, and other sources.

Pyrites and Other Metal Sulfides

Metal sulfides, widely distributed in nature, have long been an important source of sulfur. Sulfide ores of commercial interest for their sulfur value alone belong to the ferrous group collectively known as pyrites. The most important of these are the minerals pyrite, marcasite, and pyrrhotite. Pyrites commonly contain traces of nonferrous metals (Russell 1989). Pyrites once were mined in many countries specifically for their sulfur content, but they have decreased in importance globally.

Sulfur is also recovered (ultimately as sulfuric acid) from nonferrous metal sulfides that are mined and processed for their nonferrous metal content. The most important nonferrous metal sulfides include those of copper (chalcopyrite, chalcocite), lead (galena),

zinc (sphalerite), molybdenum (molybdenite), nickel (pentlandite), mercury (cinnabar), arsenic (arsenopyrite, realgar), antimony (stibnite), and silver (argentite and various sulfosalts). Associated iron sulfides are also recovered as a by-product flotation concentrate during the processing of nonferrous ores. This source of pyrite has displaced some voluntary pyrite sources, but it also depends on the market for nonferrous metals.

Ferrous and nonferrous sulfides are the leading source of sulfur production in Australia, Chile, China, Finland, India, the Republic of Korea, and Spain. Large quantities of by-product sulfides are produced in Canada, Germany, Japan, Mexico, Russia, and the United States. China and Finland are the only countries where the major source of sulfur is pyrites; all the other countries listed produce sulfuric acid as a by-product of metal smelting.

Sulfide ore deposits occur in a variety of geological environments. Mineralization occurs in massive lenses, tabular masses, and veins, and disseminated throughout a variety of rock types. Pure pyrite contains 53.4% sulfur and 46.6% iron. Commercial-grade pyrite ores are usually between 40% and 50% sulfur and frequently contain small amounts of arsenic, lead, copper, cobalt, gold, zinc, thallium, and other trace elements. These associated nonferrous metals can be recovered as a by-product, but they can also be a source of environmental problems.

Pure pyrrhotite has varying chemical compositions, but it is poor in sulfur relative to pyrite. When pure, it contains about 38% sulfur and 62% iron. Pyrrhotite is softer than pyrite and weakly to strongly magnetic. Cobalt, nickel, and copper are frequently found in association with pyrrhotite. Silver, gold, platinum, and other trace elements are less common.

Pyrites were the second major source of sulfur in the mid- to late-19th century following the rise in the price of Sicilian sulfur. Pyrites lost predominance to Frasch sulfur in the early 20th century, and pyrite production continues to decline. In 2003, pyrites supplied 7% of the world's sulfur in all forms, down from 17% in 1990.

One of the major reasons for this decline is the capital investment required for a pyrite-based sulfuric acid plant, which is two to three times that required for a comparable plant based on elemental sulfur (Loughborough 1991). Environmental problems have also plagued pyrite producers, because the disposal of cinder residues from pyrite processing is a great obstacle. These factors, coupled with the increasing availability of elemental sulfur, have resulted in less production from pyrites. Several acid plants in Europe and China were converted from pyrite-based to elemental sulfur-based, leaving very little pyrite-based sulfuric acid capacity anywhere except China and Finland. Even in those countries, pyrites continue to decline.

Sulfur is also recovered during the smelting of nonferrous sulfides. Sulfur dioxide in the smelter gases is converted to sulfuric acid, liquid sulfur dioxide, or oleum. The manner in which these concentrates are processed is similar to the way that pyrite is treated, but sulfur recovery can be more difficult because of widely varying sulfur contents in fluctuating gas streams. This source of sulfur has been increasing in significance as a result of progressively tighter antipollution legislation. By-product sulfuric acid represented 21% of all global sulfur production in 2003, an increase of nearly 62% since 1990, when it was 13% of total sulfur production.

In the United States, by-product sulfuric acid from the nation's nonferrous smelters and roasters supplied about 7% of the total domestic production of sulfur in all forms in 2003. This figure has decreased steadily since 1998 because several U.S. copper smelters have closed as a result of poor copper metal prices and preference of lower-cost copper leaching processes. In 1990, seven acid plants operated in conjunction with copper smelters, and eight

were accessories to lead, molybdenum, and zinc smelting and roasting operations; in 2003, three copper smelters and three other smelters reported by-product sulfuric acid production (Ober 2004).

Sulfur Dioxide Emission Control

In addition to being a commercial source of sulfur, sulfur dioxide is also one of the most common synthetic pollutants. Human activity released about 142 Mt of sulfur dioxide containing 71 Mt of sulfur into the atmosphere in 2003. The leading source of this pollution is the burning of coal to produce electric power (Anon. 2004f). Although these fuels often contain low percentages of sulfur by weight, large quantities of fuel are burned by utilities and industrial users, discharging large quantities of sulfur in dilute gases.

Much of the remaining synthetic emissions come from the smelting of nonferrous ores. Pyrometallurgical operations emit higher concentrations of sulfur dioxide than do power plants, but there are many fewer installations worldwide.

The environmental problems associated with sulfur emissions have been known and studied for some time. The downwind deposition of sulfur-bearing compounds, principally sulfuric acid, leads to acidification of lakes and streams, loss of soil nutrients, and damage to plant life. Widespread deforestation has occurred locally in Europe (where it is estimated that pollution-related disease has spread to more than half of the forested land in western Germany) and North America (Anon. 1985a, 1991b).

Sulfur compounds are but one of numerous air pollutants, but they are also one of the easiest to control, and several useful compounds can be recovered. A comprehensive review of flue gas desulfurization (FGD) methods is beyond the scope of this chapter, but the reader is referred to the FGD chapter in this book. FGD methods can be classified broadly as regenerative or throwaway processes, depending on whether the sulfur values are recovered in a useful form or disposed as solid waste. Both recovery methods can be carried out in wet or dry systems. Existing processes use a variety of compounds (lime, limestone, magnesium oxide, sodium carbonate, and others) to neutralize or collect the sulfur dioxide. End products include gypsum, sulfuric acid, liquid sulfur dioxide, and elemental sulfur, all of which can be used if local markets exist. If local markets do not exist, large quantities of gypsum or sulfuric acid may have to be neutralized or otherwise disposed of, which can create other environmental problems.

In the United States, the Clean Air Act Amendments of 1990 successfully mandated reductions in SO₂ emissions. In 2002, the last year for which data are available, sulfur dioxide emissions from power plants totaled 9.9 Mt, a 33% decrease from the 14.8 Mt emitted in 1990 (Anon. 2003a, 2004b). This was achieved by a combination of alternative clean fuels such as natural gas and low-sulfur coal and innovative FGD technology.

Pollution control legislation, by requiring the neutralization and recovery of environmentally damaging compounds, effectively provides additional quantities of sulfur to the market regardless of the economic viability of these activities. As pollution legislation has continued to tighten, increasing quantities of sulfur have been recovered. Despite the predictions of increased tonnages of sulfur recovered from SO₂ emissions at power plants, however, the impact on total sulfur production has not been dramatic. A high proportion of the sulfur is recovered in the form of gypsum, and useful sulfur values are a very small portion of total production.

Sulfates

Sulfate minerals, particularly anhydrite and gypsum, represent the world's largest sulfur resource. Thick deposits of naturally occurring anhydrite and gypsum are found in evaporite basins worldwide, and

large amounts of gypsum are produced as by-product waste materials from a number of industrial and pollution control processes. Nevertheless, sulfates are rarely used as a source of sulfur owing to the high cost of the processing.

Sulfur values (in the form of sulfuric acid and ammonium sulfate) have been recovered from sulfate in only a few countries, including Austria, Germany, India, Pakistan, Poland, Turkey, and the United Kingdom (Anon. 1985b). Sulfuric acid is produced from anhydrite and gypsum using the Muller-Kuhne process, developed in Germany during World War I. Ammonium sulfate is manufactured from natural and by-product sulfate using the Merseberg process in which calcium sulfate is reacted with ammonium carbonate (Barker 1983).

Elemental sulfur can also be recovered from sulfate minerals, including anhydrite and gypsum, but the process has never been economic. Although there have been several attempts to design processes to recover elemental sulfur from sulfate minerals, only one commercial attempt was made in the late 1960s. Located in western Texas, the Elcor Chemical Corp. plant used gypsum from Permian evaporites in a two-step process in which calcium sulfide produced in a kiln was hydrolyzed to hydrogen sulfide, which then yielded sulfur by the Claus process. The process was energy intensive, and high fuel costs combined with technical problems and a drop in the price of sulfur caused the demise of the project (Anon. 1968, 1983; Ellison 1971). Despite occasional efforts by researchers to produce sulfur economically from sulfates, it is unlikely that sulfates will be used extensively because of the increasing availability of recovered sulfur and the relatively low price of the commodity.

Tremendous quantities of phosphogypsum, a by-product of the production of phosphoric acid, have been generated worldwide, and more than 1 Gt are stockpiled in several states in the United States, especially Florida. Much of these stockpiled compounds contain radioactive impurities (Anon 2000). Several organizations, including such groups as the Florida Institute of Phosphate Research and the Institute for Recyclable Materials at Louisiana State University, have conducted phosphogypsum utilization studies, but attempts to devise economically viable alternatives to phosphogypsum impoundment or disposal have not been successful. Recovery of sulfur from phosphogypsum can be economically feasible only if the gypsum is not radioactive and sulfur prices are extremely high, a situation that is not likely in the foreseeable future.

FORMED SULFUR

Before the early 1950s, much of the world's tonnage of export sulfur was handled as crushed bulk. Because of safety, environmental, and economic concerns arising from breakage of the solid sulfur and generation of sulfur dust, sulfur-forming techniques were developed to overcome difficulties inherent in solid sulfur operations.

Basically, liquid sulfur is formed into solid, moderately sized particles of selected shapes. These particles are designed to resist attrition, be unwettable, and handle easily during stockpiling, loading, transport, and unloading.

Early sulfur forming was limited to the production of flakes and slates, but as sulfur output from sources increased in the 1960s, so did the development of new processes for sulfur forming. A variety of forms are now produced, many of which are spherical (Raymont and Hyne 1983).

Production of Formed Sulfur

The main purpose in sulfur forming is to prevent breakage of the solid sulfur particles during handling. Two factors emerge as the most important in determining resistance to breakage: particle size and sphericity (Hyne 1990). The larger the particle size, the greater

the tendency to break apart during handling (friability). The optimum size for spherically formed sulfur is between 1.5 and 3.5 mm. Sphericity is also important in that the more spherical the form, the less likely it is to have easily ruptured protrusions. These factors are especially important in the so-called premium products, where fines (less than 0.3 mm) or dust production is required to be less than 2%. Highly spherical products, however, will have a low angle of repose and angle of climb (the maximum inclination that can be used to lift a product on a conveyor belt without it running back), which may generate other problems during transportation and storage.

Reduced friability also reduces the environmental impact of solid sulfur handling. On exposure to water and air, elemental sulfur reacts to form sulfurous and sulfuric acids, which can create localized environmental problems and lead to excessive corrosion of plant facilities. The reaction is bacterially mediated, and the rate of reaction is inversely proportional to the sulfur particle size. The production of acid can be minimized if dust levels are controlled or bactericides are used.

Sulfur is made into several primary forms: flakes, slates, prills (or pellets), nuggets, granules, pastilles, and briquettes. Flakes are the easiest, but least popular, of the forms to produce. Sulfur is cooled and solidified on the outside of large rotating drums, from which it peels off into small flakes (Anon. 1979b).

Slating, the least expensive process, is widely used but also produces particles having relatively high friability. Molten sulfur is cast onto a continuous conveyor belt and is cooled with air or water so that it solidifies into a thin sheet. As it reaches the end of the belt, the sheet is broken, or breaks naturally, into smaller pieces.

Prilling sulfur is a more complicated forming method, but it also is widely used. There are two fundamental types of sulfur prilling—air and water. In air prilling, molten sulfur is sprayed from the top of a tower against an upward flow of air. As it falls, the sulfur breaks into small droplets and cools into prills. In water prilling, the sulfur is sprayed into tanks containing water, from which the prills are collected and dried. Prilling is also referred to as pelletizing, a legacy from the production of lead shot in towers. Minor modifications to prilling techniques are used to produce nuggets.

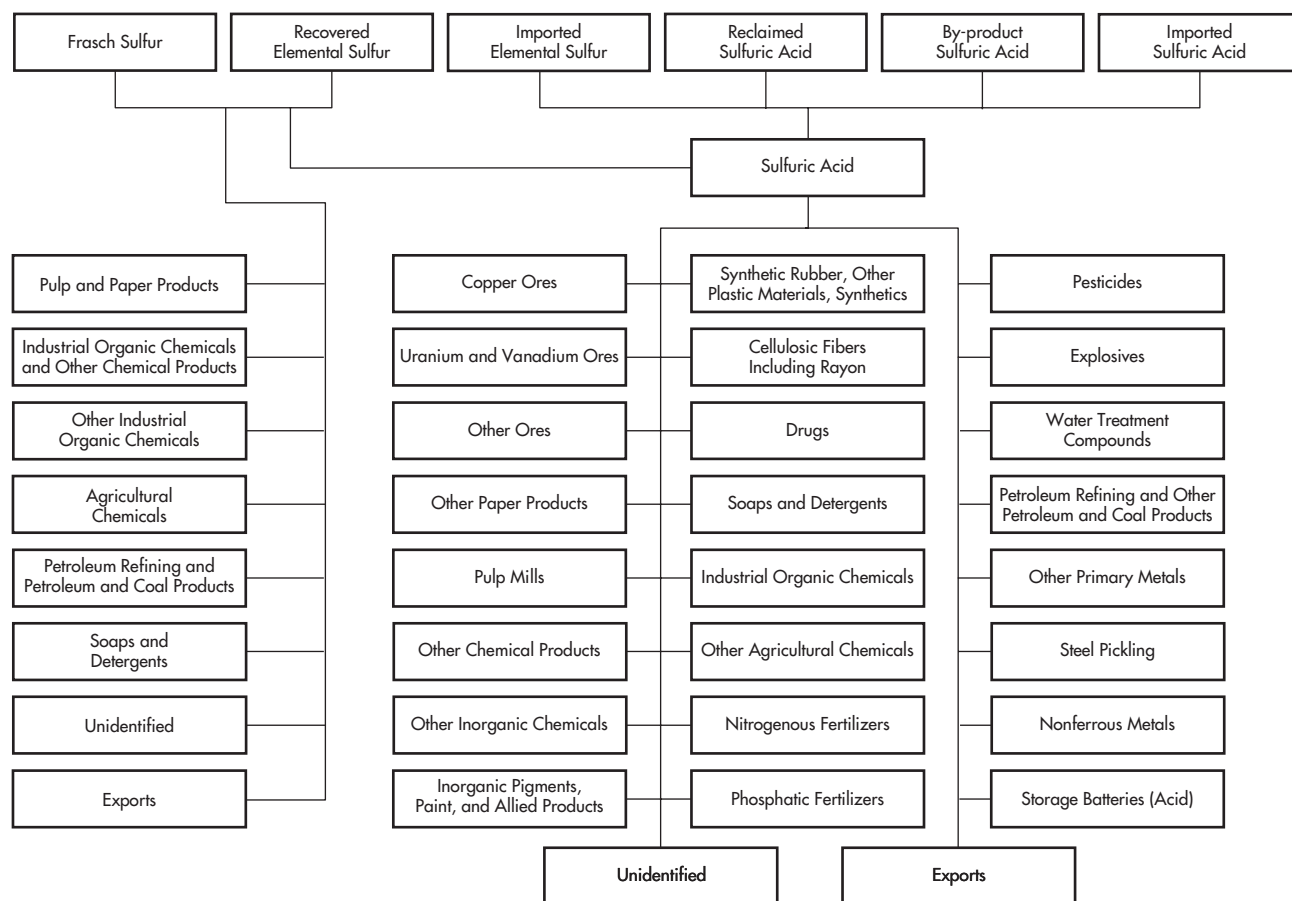

Granulation involves applying successive coats of sulfur to solid particles of sulfur in a granulator until the particle size reaches the required value. In the GX granulation process of Enersul Ltd., liquid sulfur is sprayed into a rotating drum in which small seed particles of sulfur are recycled from the end of the process (Hyne 1990). The product granules are spherical, dry, hard, and free from the voids and structural weaknesses often associated with prills. The end product size can also be varied to meet customer requirements.

Pastilles are individual droplets of molten sulfur that have been dropped on a steel belt and cooled by conduction. Sandvik A.B. has a Rotoform process that uses a patented Rotoformer (essentially a perforated drum) to distribute the sulfur on the belt. At the end of the belt, the pastilles are scraped off and fall onto a collecting conveyor. The resulting pastilles are spherical but flattened on one side.

Characteristics of Formed Sulfur

The characteristics of the sulfur form have a direct bearing on the suitability of the form for transport. Important characteristics include friability, moisture performance, and handling characteristics; friability is probably the most important (Anon. 1979b; Raymont and Hyne 1983). The friability of a sulfur form is influenced by the particle size, surface texture, internal voids, and crystallinity.

Moisture performance is defined by the moisture content of the newly formed product and the moisture uptake and retention when it is stockpiled. Those forms produced by water quenching

Source: Ober 2002.

Figure 14. Sulfur-sulfuric acid supply and end uses

have a higher initial moisture content than forms produced by dry processes, but mechanical dewatering and drying can reduce the moisture content. The moisture uptake and retention of a sulfur form are particularly important because stored sulfur is commonly exposed to the atmosphere. Formed sulfur usually has reasonable water rejection properties because sulfur itself is hydrophobic. The spherical forms exhibit superior water rejection properties; water will often penetrate only the first few centimeters into a stockpile and then drain away.

The handling characteristics of a sulfur form depend on particle size and shape, uniformity, surface texture, density, and hardness. The properties of bulk density and the angle of repose are two of the most important handling characteristics. Normal dry bulk sulfur has a bulk density of between 1,345 and 1,440 kg/m³ and an angle of repose of 35°. Formed sulfur should have a density approaching bulk sulfur and as high an angle of repose as possible, but these values vary considerably, even for forms produced by the same technique. The density and angle of repose are also affected by the moisture content.

REFINED SULFUR

The category of refined sulfur includes a wide range of manufactured products, of which ground sulfur is the most prominent. Sometimes referred to as specialty sulfur, this category also includes wettable, insoluble, precipitated (also referred to as sublimed or flowable sulfur), colloidal, micronized, and double-

refined sulfur, along with special grades used in manufacturing pharmaceutical and photochemical products (Anon. 1979a, 1992).

Although refined sulfur is the oldest end use of sulfur—having been used since antiquity, particularly in pharmacology and alchemy—demand for refined sulfur continues to grow. Nevertheless, of all the sulfur consumed in the western world, only a very small percentage is used as refined sulfur or specialty grades. Even so, it is a business that is important in its own right because it supplies essential and highly specialized products for agriculture and industry.

Although ground and refined sulfur are used to some extent almost everywhere in the world, the manufacture of ground and refined sulfur is confined to a relatively small number of enterprises, most of which are concentrated in areas where the level of economic development is high, such as North America, Europe, and Japan. Other producers are found where there is significant domestic demand, such as Australia, the Republic of South Africa, India, Mexico, Brazil, and Chile, or where large quantities of recovered sulfur are available for export, such as Kuwait and Saudi Arabia (Anon. 1984b).

Ground sulfur must be manufactured in highly controlled conditions to prevent explosions. Because ground sulfur will autoignite at 190 °C, grinding is done in an inert atmosphere with special equipment to minimize the buildup of heat and static electricity.

A healthy international trade in refined sulfur exists because almost all economies need sulfur, but not necessarily enough to justify establishing a domestic industry. In general, the pattern of

trade is from North America to South America in the Western Hemisphere and from Europe and Japan to nonproducing countries in the Eastern Hemisphere.

END USES

Sulfur is consumed mainly in the form of acid and, to a lesser extent, other intermediate chemicals used to manufacture a final product that often does not contain much, if any, sulfur. Approximately 90% of all sulfur consumed in the United States every year is in the form of sulfuric acid for use in a multitude of industries. The balance is used for a variety of nonacid industrial purposes. Figure 14 and Table 5 give detailed end-use information for the United States.

The largest single use of sulfur is in the production of phosphate fertilizers, followed by petroleum refining, other agricultural chemicals, copper ore leaching, and other industrial uses. Combined agricultural uses of sulfur in all forms account for 62% of identified domestic use.

Sulfuric Acid

Sulfuric acid, because of its desirable properties, is the most universally used mineral acid and the largest-volume inorganic chemical in terms of the quantity produced and consumed in the United States (Ober 2004). World sulfuric acid production totaled about 159 Mt in 2003 (100% sulfuric acid), of which 41 Mt containing about 13 Mt of sulfur was produced in the United States.

The reasons for sulfuric acid's dominance as the most desirable mineral acid are as follows (Shelton 1980; Barker 1983):

1. Raw materials and acid plant operating costs are low.
2. Shipping, handling, and storage problems are fewer than for other acids.
3. The acid adapts to numerous acidulation and neutralization processes.
4. It has excellent dehydrating properties.
5. It demonstrates effective catalysis in many hydrocarbon and organic chemical syntheses.

6. It readily forms organic sulfates with many hydrocarbons, which are easily hydrolyzed to form other basic products.
7. It has a high boiling point, which limits volatilization losses caused by high temperatures required in many processes.
8. It can be partially used in one process, reused in a second or even a third process, and be readily regenerated, fortified, and concentrated for still further uses.

The basic equations for sulfuric acid production are the same regardless of the process used or the source of the sulfur. The reaction sequence goes as follows

Actual production is much more complicated than this and processes vary significantly, as do requirements for different sulfur sources.

The earliest commercial process for sulfuric acid production, the chamber process, was first used in 1746 (Sander, Rothe, and Kola 1984). In this process, oxides of nitrogen acted as catalysts for the oxidation of sulfur dioxide to sulfur trioxide in a lead chamber reaction vessel. Because the maximum concentration of the sulfuric acid product from the chamber process is about 77% to 78%—lower than that produced in most industrial facilities—the process is considered obsolete, with very limited production from plants of this type (Donovan and Salamone 1983).

The contact process replaced the chamber process early in the 20th century because it could produce the much more concentrated acid (about 98%) needed in the production of synthetic dyes, organic chemicals, and the explosives required during World War I. The first contact process, using a platinum catalyst to oxidize sulfur dioxide to sulfur trioxide, was developed in 1831. It continues to be used with improvements, especially in the type of catalysts used. Eventually vanadium pentoxide replaced platinum as the dominant catalyst, owing to its insensitivity to catalyst poisons and its lower cost; a cesium-promoted vanadium catalyst was a later innovation. A second absorption stage was added in the contact process, optimizing the efficiency of the conversion of sulfur dioxide to sulfur trioxide, reducing sulfur dioxide emissions significantly, and improving the environmental performance of modern sulfuric acid plants. Nearly all sulfuric acid plants in developed countries use double-absorption systems to comply with environmental regulations limiting sulfur dioxide emissions at chemical operations (Sander, Rothe, and Kola 1984). Typical double-absorption plants, as shown in Figure 15, recover 99.5% to 99.8% of the sulfur dioxide produced at the sulfur burner, and some are even more efficient (Donovan and Salamone 1983). Single-absorption contact plants can treat their tail gas, sometimes by producing ammonium sulfate to meet environmental standards.

Smelter-based sulfuric acid plants use the double-absorption process to strip their off-gases of sulfur dioxide. The biggest difference between sulfur-burning and by-product sulfuric acid plants is the lack of a sulfur burner at smelters. Smelter gases have lower sulfur dioxide content and more impurities, requiring slightly different steps and higher gas-flow capabilities to produce comparable quantities of sulfuric acid.

Agricultural Uses of Sulfur

More sulfuric acid is consumed in converting phosphate rock into phosphoric acid and other phosphate fertilizers than is consumed in any other industry. Sulfuric acid converts the insoluble phosphate

minerals into phosphoric acid that can then be used directly or processed into more complex fertilizers. Ammonia and sulfuric acid combine to form ammonium sulfate, another fertilizer that requires sulfur for its production. Elemental sulfur products have been developed to provide sulfur for crop nutrition. Other agricultural uses that require elemental sulfur include nutritional supplements in animal feeds and salt blocks. Finely divided sulfur is also used in agriculture as fungicides, insecticides, and miticides.

In agriculture, refined sulfur in powdered (dry or wettable), micronized, sublimed, and other forms, often combined with metal compounds, is used in direct application on crops, in viticulture, and in horticulture as protection against mildew, powdery mildew, and other fungi. In these end uses, however, crude recovered sulfur increasingly is used without being refined because the quality of recovered sulfur is sufficient.

Refined sulfur, mainly ground, is also used in wine and sugar refining, as a pesticide (since ancient times), in fertilizer as a soil conditioner, and as an additive to compound animal feeds. Plant nutrient sulfur (PNS) products formulated from refined sulfur deliver small sulfur particles that decompose more readily into the sulfate form. The particles can be agglomerated into granules with a binding material that makes the sulfur easier to handle, limiting the sulfur dust, and improving the safety of handling finely divided sulfur. Other products incorporate elemental sulfur with 10% bentonite clay. After application, the clay swells as it absorbs soil moisture, breaking off the sulfur in a variety of particle sizes (Anon. 1999b).

Industrial Uses for Sulfur

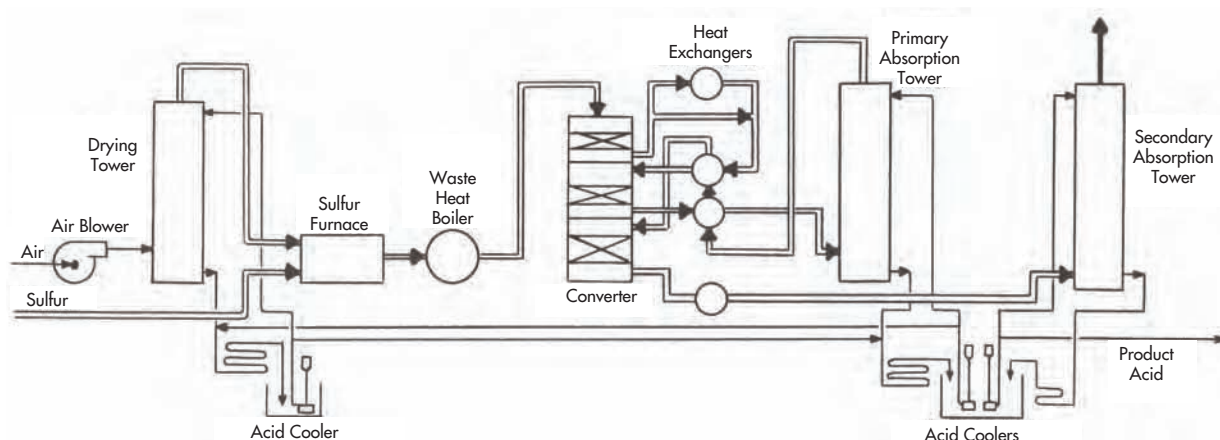

In addition to being the largest source of recovered sulfur in the United States, petroleum refining is a large consumer of sulfur in the form of sulfuric acid. Refineries use sulfuric acid in the alkylation process, which combines specific hydrocarbon materials to produce high-quality gasoline. In nonferrous metals production, processes have been developed that dissolve the various metals from the host rock with sulfuric acid and then recover the desired metals from the solutions. Copper has been produced through a solvent extraction–electrowinning (SX–EW) process since about 1967. Nickel can be produced using a pressure acid leach process.

Another industrial use of sulfuric acid is the source of one sulfur compound used in agriculture. Ammonium sulfate is a by-product from the production of caprolactam, an organic chemical that is a precursor for the nylon-6 polymer that is used in carpets, other textile products, and plastics. Through a series of complex reactions, sulfur, ammonia, and benzene combine to form caprolactam and ammonium sulfate. This process is unusual in that as it consumes sulfuric acid, it produces a usable sulfur by-product—ammonium sulfate, which is used in agriculture.

Although not currently widely used, sulfur construction materials can offer improvements over more conventional materials, especially in specific applications. Sulfur construction materials include sulfur concrete, sulfur-extended asphalt pavements, precast concrete components, extrusions, and cast-in-place forms. Other major end uses for sulfur and sulfuric acid are hydrofluoric acid production, pulp and paper processing, and titanium dioxide production.

Smaller end uses include vulcanization of natural and synthetic rubber tires, production of explosives and other organic and inorganic chemicals, steelmaking, and the production of synthetic rayon fiber. The electrolyte in lead–acid batteries is sulfuric acid.

In industry, the rubber and tire sector is the prime user of special sulfur, using ventilated, micronized, and insoluble forms, all of which are necessary in the vulcanization process. Much smaller quantities of specialty grades are used in the manufacture of such diverse items as pharmaceuticals, matches, fireworks, and textiles.

Source: Barker 1983.

Figure 15. Simplified flowsheet, double-contact sulfuric acid plant

Many other processes use sulfur and sulfuric acid, but listing all of them would be nearly impossible.

Uses for Sulfur with Potential for Growth

Various industrial, academic, and governmental groups have been researching expanded uses for sulfur for some time. The growing supply of sulfur in both elemental and combined forms has led to the development of a number of new products. The use of sulfur in construction applications possesses the largest potential for new sulfur consumption. The practicality of these applications is largely a function of the price of sulfur in relation to competing materials.

Many products have been researched, and some are currently in use. The most promising construction uses are sulfur-extended asphalt paving applications, which give increased durability and performance over a wider range of temperature, and sulfur polymer concrete, a paving or construction material that uses a modified sulfur binder with conventional aggregates. Other construction uses include an extender or recycling agent for used asphalt; foamed sulfur with high compressive strength and insulating properties to be used for insulation, pavement subbases, and possibly lightweight structural applications; an impregnator of various compounds to increase strength, durability, and water resistance; a coating mixed with fibers or modifiers on block or brick buildings, linings for ponds, and other applications where a durable coating is useful; sulfur concretes, mortars, and aggregates with enhanced corrosion and salt resistance; and molded sulfur blocks for tile and brick. Other research has tested using sulfur in electrodes in alkali metal batteries and in sewage and wastewater treatment (Muir 1982; Terrel 1982; Barker 1983).

Paving materials containing sulfur have been shown to possess superior qualities to more conventional paving materials in tests at numerous sites but have enjoyed limited commercial application. In sulfur-extended asphalt, up to 30% of the asphalt binder is replaced with elemental sulfur, making pavement with increased stability, reduced rutting, and increased resistance to cracking at low temperatures (Keenan 2003). Sulfur concrete has several attractive properties that make it superior to portland cement concrete in some applications. These include strength and durability; short setting times and rapid achievement of full strength; impermeability; resistance to corrosion from acids and salts; and high electrical resistivity. Sulfur concrete is particularly effective in high-corrosion environments

such as industrial flooring, acid storage tanks, electrolytic cells, sewer pipes, and bridge decking (Pickren and Mollère 2002).

Copper SX-EW operations are expanding around the world, especially in Australia, Chile, Peru, and the United States. With large reserves of leachable copper ores identified around the world, SX-EW processing holds the potential for significant growth and, with it, significant increases in sulfur and sulfuric acid consumption (Gillen 1996).

In the nickel pressure acid leach (PAL) process, sulfuric acid reacts with nickel laterite ores under high temperature and pressure to dissolve the nickel from the minerals. Large quantities of sulfuric acid are required to recover nickel from the ores, averaging about 30 t of acid per ton of nickel produced. This end use could add significantly to sulfur and sulfuric acid demand, but detailed and specific forecasts are not available.

ECONOMIC FACTORS

Costs

Economic factors and costs of production in the sulfur industry must be considered separately for the voluntary and involuntary producers. As with most industrial minerals, the voluntary sulfur industry is market driven. The degree of use of sulfur and sulfuric acid depends on worldwide economic activity and the health of industries that use sulfur-bearing compounds for the production of other goods. That is not entirely true for involuntary producers who must recover sulfur if their primary operations are to remain active.

What remains of the voluntary sector of the sulfur industry is based on the orderly mining of discrete deposits of native sulfur to obtain as nearly a complete recovery of the resource as economic conditions will allow (Morse 1985). This requires a relatively assured market and a price structure attractive to both producers and consumers. The assured market is commonly based on the relatively close proximity of sulfur users, frequently fertilizer production centers, and the availability of cheap transportation to end users. To a significant extent, stability of sulfur supply and price is accomplished by the maintenance of large stocks of sulfur by the producers.

For the Frasch producers, the main operating expenses are fuel for heating the process water, chemicals for treating the water, and the cost of drilling production wells. Work-force requirements are relatively low. Additional costs include plant maintenance,

royalty payments to landowners (frequently a significant cost), taxes, and transportation. High fuel costs or excessive subsurface water loss can increase the cost of sulfur recovery to a point where it is no longer profitable to operate the plant.

In contrast, involuntary producers are often forced to recover sulfur from their primary product because of environmental restraints or other mandates. The economic desirability of producing sulfur is often subordinate to the necessity of recovering it, and the sulfur revenues may represent only a small portion of the revenues (sometimes not even enough to pay for recovery) from the primary product. In such cases, there may be no ready market for the sulfur or sulfuric acid, and the producer may be forced to dump the product on the market regardless of the cost. The sulfur may also be transported to a market far from the source, and so the transportation charge constitutes a large part of the sulfur cost. Involuntary sulfur production depends on demand for the primary product, and as such is always independent of the need for sulfur.

Sulfur prices can vary greatly by location, source, and terms. In late 2004, *Fertilizer Markets*, a weekly fertilizer industry newsletter, published sulfur prices that ranged from \$50 to \$93/t (Anon. 2004e). *Green Markets*, a similar publication, reported prices ranging from \$12 to \$74/t for other locations (Anon. 2004c). Tampa, Florida, Frasch prices were once the standard against which the prices for all other markets were compared. Frasch sulfur once demanded a premium price because of its superior quality to recovered sulfur, but recovered sulfur has improved to a level comparable to Frasch and its availability to the point that no separate prices are published. As the Frasch industry declined, so has its dominance in sulfur pricing strategy.

By 1990, world sulfur price leadership had shifted from U.S. Frasch producers to the Canadian recovered sulfur exporters. This shift was aided by the ability of Canada to export most of its production from the Port of Vancouver and to ship large volumes from vatted stocks. The abundance of sulfur exporters has diluted the ability of any one industry segment to influence prices. International sulfur trade has become quite competitive, and consumers sometimes have the upper hand in price negotiations.

Markets

The international market for elemental sulfur is active and growing. In 2003, world sulfur trade was 24 Mt, representing 54% of all elemental sulfur produced globally, compared to 1990 when 17 Mt (44% of global production) was traded internationally. The exporters with more than 1 Mt in 1990 were Canada, Poland, Saudi Arabia, and Mexico. The leading exporting countries in 2003 were, in descending order of export tonnage, Canada, Russia, Saudi Arabia, the United Arab Emirates, and Japan, all with more than 1 Mt of elemental sulfur exports.

Countries with more than 1 Mt of elemental sulfur imports in 2003 were China, Morocco, the United States, Tunisia, Brazil, and India. All of these countries use the majority of their sulfur imports to produce sulfuric acid, which is used for phosphate fertilizer production.

Sulfuric acid also is traded internationally, but to a much smaller degree than crude sulfur. Sulfuric acid trade is extensive in Canada, Europe, Japan, Mexico, and the United States (Ober 2004).

Transportation

Sulfur can be transported either in liquid or in solid states. Conversion to sulfuric acid, the principal end use, is easiest using liquid sulfur, so this has become the preferred form, especially when environmental effects are considered. When sulfur cannot be transported to a consumer in the liquid form, it is converted to a variety

of solid forms for transportation or is stockpiled. Stockpiling of sulfur is cheapest by far in large solid blocks (vats) that are broken or melted before shipment. Because sulfur block remelting is expensive, as is liquid sulfur-handling equipment, transport and handling of formed solid sulfur is often more economical except where liquid-handling facilities are in place.

Transporting sulfur in the liquid phase offers certain advantages, including ease of handling, absence of fugitive dust, and reduced losses. Unprotected personnel, however, may be exposed to hydrogen sulfide and sulfur dioxide during handling. Problems associated with solid sulfur include environmental degradation from fugitive dust, possible ignition of sulfur or explosion of sulfur dust, and corrosion of unprotected metal (Morse 1985).

Sulfur transportation costs can be a critical factor in determining the economic viability of a sulfur production facility. For example, sulfur in western Canada must be shipped to Vancouver by rail, adding a significant charge to the cost of the sulfur. Some of the oil sands operations are so remote that transportation costs have limited their availability to international markets of sulfur. The same situation exists in Kazakhstan, but pressure from government officials to reduce sulfur stocks has spurred the installation of forming apparatus to make the Tengiz material more attractive in the global marketplace.

Alternative Materials

For many uses, there are no alternative materials that can replace sulfur or sulfuric acid. In a number of diverse areas, however, hydrochloric or other acids can be substituted for sulfuric acid. The prices of these acids generally dictate which one will be used, and sulfuric acid has been the most widely used because of its relatively low cost. Sulfuric acid has been replaced by hydrochloric acid in the production of titanium dioxide. Because hydrochloric acid production costs have decreased, it could replace sulfuric acid in other applications as well. Sulfuric acid can be replaced by hydrofluoric acid in petroleum alkylation, but sulfuric acid is often perceived as safer than hydrofluoric acid (Anon. 1990c).

Environmental Considerations

Sulfur-bearing compounds, particularly sulfur dioxide and sulfuric acid, are of prime concern in legislation restricting releases of contaminants to the atmosphere and bodies of water. The broad topic of sulfur as a pollutant is well beyond the scope of this discussion, but it should be remembered that sources of sulfur pollutants are now used as sources of recovered elemental sulfur, as previously discussed.

As legislation affecting atmospheric discharge of sulfur oxides or sulfuric acid is tightened, larger quantities of sulfur (generally as acid or calcium sulfate) will be available for use in other industries. Similarly, discharges of sulfuric acid to bodies of water are increasingly prohibited. Dilute acid dumping at sea is now restricted by the European Union, and this measure, coupled with similar efforts elsewhere, has prompted an increase in the recycling of waste acid. Spent sulfuric acid was formerly neutralized or otherwise disposed of; now it is regenerated at numerous sites, where it is reburned with additional sulfur to produce regenerated acid and additional virgin acid.

Environmental concerns also affect sulfuric acid consumption indirectly. Because of environmental pressures, manufacturers of titanium dioxide (a pigment commonly used in paint) have largely converted their manufacturing process from one using sulfuric acid to a chloride-based process.

The environmental impacts of native sulfur mining and transportation are generally minimal and restricted to small areas. Frasch

mining operations commonly experience varying degrees of subsidence from sulfur removal, but at many mines, particularly in western Texas and offshore of the Gulf of Mexico, subsidence is mainly an engineering challenge. Bleedwater recovered during Frasch mining may have to be treated or cooled before it is disposed of, but in some cases water is scarce enough that the bleed water is reused. Native sulfur spilled at the surface quickly reacts to form sulfurous and sulfuric acids, which may lead to acid drainage and corrosion damage, but these effects are generally restricted in area and of short duration.

FUTURE TRENDS

Outlook for Consumption

Demand for elemental sulfur and sulfur-bearing products has continued to grow steadily as the world population and economy have grown, but temporary slumps in the market for sulfur have occurred concurrent with economic recessions. The Sulphur Institute predicts that world sulfur consumption will grow an average of 2.3% annually through 2011, reaching 74.2 Mt at that time. Fertilizer should continue as the dominant end use for sulfur, but other end uses will grow also, especially in metal leaching (Anon. 2003b).

Outlook for Supply

Production exceeded consumption in 2003 for the twelfth consecutive year, although surpluses were smaller than they had been in recent years (Kitto 2004). It appears, however, that much of the surplus is material in those remote locations that inhibit transportation to market. Stocks in Kazakhstan grew, but Canadian stocks declined for the first time in several years.

Recovered sulfur is expected to continue to increase, although reinjection projects at natural gas operations may minimize its effect on the supply/demand imbalance. North American sulfur recovery at natural gas operations has already declined as a result of depletion of deposits, but reinjection projects are likely to remove significant quantities from the market beginning in early 2005. Other reinjection plans may limit the growth in gas-recovered sulfur that could be produced at expanded operations, especially in Kazakhstan. Although not a major force in global sulfur trade in 2003, improvements to sulfur forming and handling facilities were under way, making increased availability of sulfur from Kazakhstan likely.

Sulfur production from Canadian oil sands operations will increase as more projects come on stream, but these deposits also are in remote locations with little of the necessary infrastructure to move large quantities of material to major markets. If markets do not expand in less conventional areas such as construction, oil sands companies may choose to store their sulfur underground until the markets improve. This would limit the effect that large additional quantities of sulfur produced in Canada would have on the world market.

Petroleum refiners have fewer options for disposing of excess sulfur and more potential for growth in production. Refineries are located in populated areas where large stockpiles of solid sulfur are not acceptable, and they are not close to formations amenable to reinjection of sour gases. Even in countries with a short history of environmental protection it is becoming more imperative that they reduce sulfur dioxide emissions from refineries and remove the sulfur from their finished fuels, both of which increase the production of elemental sulfur. In addition to these factors, refineries are increasingly dependent on crudes with higher sulfur content, necessitating additional sulfur recovery capacity. Thus, sulfur production from oil refineries would be expected to increase as the production of petroleum products increases, but more sour crudes, more stringent environmental controls, lower sulfur levels in fuels, and fewer

alternatives for disposing of excess supplies suggest that sulfur from this source is likely to expand at a higher rate than that of other refinery products.

In most industrialized regions, especially Japan, North America, and Western Europe, environmental regulations have resulted in very high sulfur recovery and very low sulfur dioxide emissions. Lower sulfur fuel limits and further reductions in allowable emissions are expected to add relatively small quantities of recovered sulfur. The refining of higher-sulfur crudes will have much more effect on sulfur production at refineries in these regions. In developing countries, however, more stringent environmental regulations and better enforcement of the selective laws represent the potential for very large additional supplies of recovered sulfur. In addition, these producers will face the same challenges with lower sulfur content in fuels and higher sulfur content of the crudes processed. These factors could result in tremendous increases in elemental sulfur supplies from oil refineries. A recent analysis took these factors into account and predicted that elemental sulfur recovery from oil refining could approach 50 Mt within 25 years, an increase of nearly 200% over the 17 Mt recovered from that source in 2003 (Stevens and Hernandez 2003).

Voluntary production of elemental sulfur is expected to remain relatively steady until the remaining mine in Poland ceases production. The possibility exists for Frasch production to resume in Iraq, perhaps with the assistance of the Polish producer, when conditions stabilize there, but the situation is too precarious to make a definitive prediction of what will happen.

Other voluntary production, including pyrites and other native production, is likely to continue to decline. The environmental factors that make pyrites use undesirable will continue to push consumers to alternative raw materials. Small production of native sulfur may persist where it is used for local consumption.

In conclusion, production of recovered sulfur is expected to increase steadily for the foreseeable future. Frasch and native sulfur and pyrites production is likely to continue to decrease in importance and, at some point, cease entirely unless new high-volume end uses become widely accepted.

Talc

Edward F. McCarthy, Noel A. Genco, and Ernest H. Reade Jr.

INTRODUCTION

The term *talc* refers both to the pure mineral and a wide variety of soft, talc-containing rocks that are mined and utilized for a variety of applications. Talc occurs fairly widely in a range of purities, and it is mined on every continent. The commercially exploited ores contain 20% to 99% of the pure mineral, and, although the trend is toward more upgrading and higher purity, many applications require the properties of the minerals that occur with talc.

The terms talc, *steatite*, and *soapstone* are widely used and misused in discussions of talc, its origin, and geology. Steatite was originally considered a relatively pure machinable talc, which was used in ceramic applications. Today there are two widely accepted uses of this term. In geology, *steatite* refers to a relatively pure, massive talc ore. In ceramics, *steatite* refers to a composition containing 80% talc and some fluxes, which is fired and used for electrical insulation—referred to in this chapter as *synthetic steatite*. Soapstone generally refers to a lower-purity talcose ore of mafic or ultramafic origin, which can be sawed or carved.

Talc has been used by humans for more than 3,000 years. The earliest uses were in sculpture and cosmetics. The ancient Chinese carved intricate sculptures from talc rock and made face powders using talc and rice flour. In the first century AD, the Roman philosopher Pliny referred to cosmetics made from *steatitis*. The Vikings used Scandinavian soapstone to carve pottery, many examples of which still survive. Similar artifacts from Native Americans have been found on Santa Catalina Island, west of Los Angeles.

Commercial production in North America dates from 1878 when Colonel Henry Palmer began mining talc for paper and ceramics near Talcville in western New York State. At about the same time, there are reports of small volumes of soapstone being mined in the Sierra Nevada in California for carving. Much of this early production was used for thermal insulating applications, including firebrick, stove insulation, burner tips, and wire insulators. Johnson's baby powder was introduced in the 1880s based on imported Italian powder. Commercial production began in 1904 near Johnson, Vermont; in Southern California in 1914; in Montana in 1935; and in Texas in 1952. U.S. production grew from 83,000 t in 1900 to 1.32 Mt in 1979 (Virta 2003); the major application was ceramic wall tile. A formulation based on tremolitic talc (~60%) and local clays was developed in the 1930s, and this consumed most California, Texas, and New York production well into the 1980s. That application has lessened with changing ceramic tech-

nology, and U.S. talc production has since declined to 817,000 t in 2003. Today, paper and paint are just as important as ceramics, and plastics are the most rapidly growing application.

The first true talc beneficiation plant, built in Johnson, Vermont, in 1937, used multistage froth flotation to upgrade talc ore from 55% to >95% purity. Today, this technology is used in the United States, Canada, Finland, Korea, and Brazil to produce high-grade talc from lower-grade ores.

In the early part of the 20th century, the United States imported talc from Italy and France for use in cosmetics. During World War II, these imports were replaced by domestic talc, and the United States became a net exporter to Europe, South America, and Asia. Over the last 20 years, Canada, and more recently China, have become significant exporters of talc to the United States for paper and plastics applications, respectively. In recent years, the United States again has become a net importer of talc.

In 2002, seven companies produced 817,000 t of talc from nine mines in Montana, New York, Texas, and Vermont, and 250,000 t were imported, mostly from China and Canada. Approximately 180,000 t were exported, mostly to Canada, with Mexico, Belgium, and Japan taking much smaller volumes (Virta 2004). Domestically, ceramics, paper, paint, and plastics are the major uses.

Worldwide, approximately 5 Mt were produced in 2002, with China being the major producer with 1.7 Mt. The United States, Finland, India, France, Brazil, Austria, Spain, Italy, and Australia are other countries producing more than 100,000 t each. Worldwide, paper is by far the major consumer (~40%) of talc, followed by ceramics (~20%), plastics, paint, and cosmetics. In general, world production is declining because of reserve depletion as well as replacement of talc by calcium carbonate in paper filling and by feldspar in ceramics.

The mining, beneficiation, processing, and application of talc is a sophisticated business involving geologists, mining engineers, mineral processing engineers, chemical engineers, surface chemists, and specialists in paper, plastics, ceramics, and cosmetics. In many instances, the processes and applications are unique to talc and even to specific talc deposits. The market for talc is heavily dependent on the scientific research and the technical skills of the producer. Without such applications development, the market declines. This is discussed in more detail in the Commercial Aspects and Future Trends sections later in this chapter.

Figure 1. Talc crystal structure

Figure 2. Scanning electron micrograph of talc

The Mineral Talc

Talc is crystalline hydrated magnesium silicate of the general formula $3\text{MgO} \cdot 4\text{SiO}_2 \cdot \text{H}_2\text{O}$ (see Figure 1). It is one of the layer silicates like kaolin and mica.

The adjacent layers of silica are very weakly bonded with only van der Waals forces, and this allows talc to be easily sheared along this plane. This gives it its natural slippery feel as well as its platy structure and softness (Figure 2). Talc is the softest mineral, with a hardness of 1 on a Mohs scale of 1 to 10.

When talc is split along the silica surface, the surface created is hydrophobic, or antagonistic to water. When it is fractured across the silica-brucite-silica layers, the surface created is ionic (electrically charged) and hydrophilic. Materials that have both a hydrophobic and hydrophilic component are surface active, and this gives talc its unique surface-active properties. Some types of talc are also known as soapstone, because these types are soft and have many soaplike (surface-active) properties.

Talc has a specific gravity of 2.78, a refractive index of 1.58, a specific heat of 0.208 cal/g/°C, and a thermal conductivity of 5 cal/g/sec/°C. It is relatively inert and almost insoluble in conventional acids and bases but soluble in aqua regia and hydrofluoric acid. Talc has a pH in water of 9.0 to 9.5 and very little buffering capacity because of its insolubility. Regulatory authorities consider it a nuisance dust, but it has GRAS (generally recognized as safe) status as a cosmetics and food ingredient.

GEOLOGY

Deposits

The value of a talc deposit is a function of its purity, its color, and its location relative to the market. The purity issue is not related to the absolute percentage of talc present but more a function of specific mineral or metal impurities. Asbestiform minerals and metals such as arsenic and lead are particularly deleterious even at parts-per-million (ppm) levels, and quartz, serpentine, chromium, and pyrite are harmful at levels greater than 1,000 ppm. On the other hand, carbonates and chlorite (magnesium-aluminum silicate) can be beneficial even at levels up to 50%, especially when they are white and the composition is consistent.

Origin of Talc

Although talc forms by a variety of geological processes, the origins of most talc deposits around the world are clearly defined by the host rock and the accessory minerals found with the talc. Talc deposits are divided into four types of origin: ultramafic, mafic, metasedimentary, and metamorphic. The processes associated with talc formation for each type are outlined in the list that follows.

- Type 1, ultramafic origin
 - Host rock—ultramafic rocks (e.g., peridotite)
 - Step 1—serpentinization of host; high temperature and pressure hydration with little loss of magnesium and silica to form serpentinite
 - Step 2—carbonization of serpentinite; influx of fluid containing 5% carbon dioxide to form talc and carbonate
 - Accessory minerals—magnesite, chlorite, serpentinite, mica, and sulfides
 - Localities—Vermont, United States; Ontario and Quebec, Canada; Norway; Finland; Russia
- Type 2, mafic origin
 - Host rock—mafic rocks (e.g., gabbro)
 - Step 1—serpentinization of host; hydration with little loss of silica and magnesium to form serpentinite
 - Step 2—carbonization of serpentinite; influx of fluid containing more than 5% carbon dioxide to form talc and carbonate
 - Accessory minerals—magnesite, chlorite, serpentinite, and mafic host rocks
 - Locations—Virginia, United States; Egypt
- Type 3, metasedimentary origin
 - Host rock—dolomite or magnesite
 - Process—hydrothermal alteration of host rock by influx of silica-containing fluid
 - Accessory minerals—dolomite, calcite, chlorite, quartz, and feldspar
 - Locations—Montana and Texas, United States; eastern Ontario, Canada; China; Brazil; Australia; India; France; Spain
- Type 4, metamorphic origin
 - Host rock—dolomitic or silica-containing dolomitic marbles
 - Step 1—metamorphism of host rock; subsurface temperature and pressure-driven conversions and recrystallization of the host rocks to form tremolite or actinolite within the host marble

- Step 2—steatization of the tremolite or actinolite; temperature- and pressure-driven alteration of the tremolite to talc and carbonate
- Accessory minerals—tremolite, carbonate, serpentine, actinolite, and quartz
- Locations—New York, California, and Georgia, United States; Italy (Val Chisone)

The formation of talc types 1 and 2 is almost identical. The basic reaction is

Mafic and ultramafic rocks are dark igneous rocks that are high in magnesium and iron and lower in silica. The products formed are high in iron (5% to 10%), and the magnesite is an iron isomorph. The mafic products are lower in talc content (15% to 35%) and generally useful only for carving or dimension stone. The ultramafic products have 30% to 70% talc and large crystal sizes (>100 µm) and are usually quite platy (high aspect ratio). The latter property results from the folding and fluid movement that takes place during the formation. The stoichiometry of the previous basic talc-forming reaction will give a talc content of 50% to 60%. A further enrichment of talc can take place if the talc-carbonate close to edge of the ore body reacts with silica-rich fluid in the host rock. This process is called “steatization” by geologists and can result in a narrow zone of up to 90% talc near the edge of the ore body. The whole process is called “steatization of serpentinite,” and the ores are often called soapstone or lairdstone. The higher talc content products are often used as is or upgraded to >95% talc purity by froth flotation.

The talc in ultramafic-type ores has high levels of iron and other heavy transition metals (nickel, chromium). Most of these metals substitute for magnesium in the talc lattice and cannot be removed. They are not available and are not toxic, but they do account for the green/blue cast of the pure talc and contribute to the strong brown color when the talc is weathered or fired.

Ultramafic is the most abundant deposit worldwide, but metasedimentary is by far the most widely exploited commercially and accounts for more than 70% of world production.

Metasedimentary deposits vary widely in purity and composition from <25% talc in some of the magnesite rocks in Brazil to >95% talc in some of the massive deposits in Montana and China. The basic reaction that forms most deposits is

This reaction would indicate that most talc of this type would be a minor ingredient in a calcite rock. In fact, few deposits have large amounts of calcite associated with them, as the hydrothermal fluids that introduced the silica are believed to have removed the calcite.

A second type of metasedimentary deposit is found in France, Sardinia, and Austria where magnesium-rich fluids altered mica schists to form chlorite, and the silica released during this reaction altered overlying dolomite to talc. These deposits have 25% to 75% chlorite along with the talc and are often referred to as chloritic talc.

Metamorphic deposits were at one time the most commercially important deposit type in North America. The basic reaction is

These deposits are quite variable in talc purity from ~30% in New York State to >70% in Madoc in Ontario. Associated minerals also vary in their levels, with carbonate being the major impurity in

the Madoc deposit in eastern Ontario and tremolite in New York. Tremolite, a calcium magnesium silicate, can occur in either blocky or prismatic forms. The prismatic structure results in a powder that has good dry pressing properties for ceramics. Because the ores are typically very low in iron content, they are white (good for paint) and they fire white (good for ceramics). Tremolite is also a much harder mineral than talc and will build a lower viscosity in suspensions. This property is valuable in paint.

Distribution of Major Deposits

In this section, the focus will be on commercial deposits that are presently being exploited, with lesser emphasis on either historically important or other known deposits.

North America

In the United States, talc is mined in Montana, New York, Texas, and Vermont. In Canada, talc is mined only in Ontario, with minor soapstone production for carving and stove liners in Quebec. Montana has overtaken Texas as the leading producer because of (1) the growth in paper and paint applications, for which Montana products are best suited; and (2) a decline in the older wall tile production technology, which is the biggest market for Texas talc.

Montana. Major massive talc deposits occur in the Gravelly and Ruby ranges of southwestern Montana. The talc is of metasedimentary origin in a carbonate host rock. Deposits range from thin (<1 m thick) veins to massive (100 m thick) pods of steatitic talc. The deposits were first mined under ground in the late 1930s as a source of machinable steatite ore for defense purposes. Today three major open-pit mines produce approximately 400,000 tpy of mostly high-purity talc for paper, paint, ceramic, and plastic applications. Waste-to-ore ratios are quite high at greater than 6:1 in all cases.

The talc was formed by the hydrothermal replacement of magnesium-rich marble. Silica-rich fluids penetrated the marble, reacted with the dolomite, formed talc, and swept away most of the excess calcium carbonate. Cross-cutting fault zones and joints serve as ore-forming fluid conduits and often contain minor blooms as subsidiary veins of talc.

The talc in the Yellowstone mine in the Gravelly Range southwest of Ennis is very fine grained and white to light green in color with yellow staining in the weathered or oxidized zones. Dolomite and quartz are the major impurities, with minor amounts of chlorite, pyrite, iron oxides, and dendrites of manganese minerals.

The talc can occur in high-purity thin (<1 m) veins in dolomite or as thick (>200 m) pods of botryoidal form. The talc was formed during the Proterozoic era or approximately 1,700 million years ago. Economic reserves at the Yellowstone mine are in excess of 40 years at present rates of production.

The other major mines are the Regal and Treasure mines in the Ruby Range in Madison County near Dillon. This ore is not as fine-grained as the Yellowstone mine ore, is white to gray in color, and occurs in lenses of 1- to 5-m thickness in a dolomite host rock. Chlorite is a major impurity along with dolomite, quartz, and magnesite. Pyrite, graphite, mica, and titanium are minor components.

New York. Metamorphic talc ores are mined from the Precambrian Grenville Province in northwestern New York near the towns of Gouverneur and Balmat. In the early years of these mines, which have been exploited since 1878, underground mining was mainly used, but operations are now consolidated into two open-pit mines. The ores are highly tremolitic; typically 60% tremolite, 30% talc, and 10% serpentine. They are very white, low in iron, and occur in both thin veins (2 to 5 m) and thick seams (40 to 80 m) over a

13-km-long, 150-m-wide belt. The host rock is a marble with some gneiss. Zinc deposits also occur in the vicinity, and talc contamination was a major problem in the beneficiation of the zinc ores.

Product applications are focused on paint, with ceramic tile, once a major market, now declining in volume because of technology changes. That, along with health concerns about tremolite, accounts for the decline in production in this area over the last 20 years.

Texas. The major talc production in Texas is from the Allamore Formation near Van Horn in west Texas. The formation is approximately 32 km in length and 8 km wide with talc occurring very close to or at the surface, in thick (10 to 500 m) seams in a host marble and phyllite rock. The talc is of metasedimentary origin and quite unique in that most of it is very dark gray or black. The ore is typically 80% to 85% talc, 10% to 12% carbonates, 2% to 4% quartz, and 0.1% to 0.7% graphite, which accounts for the black color. It is very low in iron content (<0.3%) and thus fires white. Smaller zones of pink to white talc occur and are mined for color-sensitive applications.

The major market for west Texas talc has always been ceramic tile. Because low-cost natural gas is available for firing, the tile industry has become concentrated in the southwestern United States and across the Mexican border in Monterrey. Although tremolitic talcs—well suited for pressing into tile—had been available from California and New York, the low cost and proximity of the Texas talc made these deposits more attractive. It was found that if some of the talc was calcined in lump form and then milled with the raw ore, a much more pressable mixture was produced. This became the standard for west Texas talc.

In recent years, production has steadily declined as ceramic tile technology changed, and talc is used now more as an additive than as a major component of tile body raw materials.

Vermont. Vermont has produced talc for more than 100 years. In the late 1800s, soapstone was mined in Vermont and New Hampshire and cut into blocks for stoves and heating utensils. Production of talc powders began in Johnson, Vermont, in 1904. At one time, seven mines were active in the state, but production is now limited to one, the Argonaut, near the town of Ludlow in central Vermont. The Vermont deposits are part of the Appalachian Orogenic belt, which extends north into Quebec and the Superior Province of eastern Ontario. Similar deposits are found in Norway, Finland, and the province of Karelia in Russia.

Talc was formed from the alteration of peridotite (ultramafic) rocks of Precambrian age, first into serpentine and then to talc and magnesium carbonate by reaction with carbon dioxide. Talc-carbonate mineralization generally is found as an alteration zone rimming a serpentinite core. The deposits vary in size from 1 m wide by 200 m length to 150 m wide by 1.5 km length. The margins of the deposits usually have a thin blackwall containing a biotite-chlorite schist in contact with the surrounding host peridotite. Subsequent shearing has complicated the structures and created zones of high-grade platy talc. Grades typically run 45% to 70% talc, with magnesite, chlorite, serpentine, quartz, and mica being the major impurities. Minor amounts of magnetite, chromite, nickel sulfides, and manganese minerals are scattered in the deposits.

Along with the Ludlow deposit, talc has been mined near Johnson, North Troy, and Waterbury in northern Vermont and in Windsor and Chester in southern Vermont. Vermont talc is crushed and milled as a whole ore for use in rubber, roofing, flooring, and other construction products. Some talc ore was also purified by froth flotation for use in cosmetics and reinforcing plastics, but that is now uneconomic. Environmental activism, directed at both the mining and transport of talc, is strong in Vermont and has hurt the industry in the past 20 years.

Other U.S. Production

Over the years, California and Georgia have also been major talc producers, and Arkansas, Alabama, Maryland, Nevada, North Carolina, Oregon, Virginia, and Washington have had limited production, but other than some intermittent campaigns on old mines and tailings piles, production in these states has ceased today. Only limited discussion of these deposits will be given here, but the reader is referred to a report by Greene (1995) for a more complete description.

In southeastern California, the Inyo or Talc City district was a major producer of high-purity steatite talc from underground mines from 1914 until 1978. This metasedimentary-type deposit produced a very white and very machinable grade of talc. Further east, the Southern Death Valley–Kingston District produced, from the late 1920s to the late 1980s, a very white tremolitic talc, valued for its properties in ceramic tile and industrial coatings, especially marine paints. In the northern Sierra Nevada foothills, small, altered ultramafic deposits were mined until 1997 for roofing and construction products. Similar small deposits have been mined in Oregon and Washington states for soapstone blocks.

In Georgia, deposits of the metamorphic type were mined underground in the Chatsworth Area until 1990. Roofing and construction were the major uses, and a froth flotation plant was built in 1987 to make products for paper and plastics. The project failed because of the inability to produce a high-brightness product and the failure to effectively remove tremolite from the talc. In Talladega County, Alabama, a small metasedimentary-type deposit was mined from 1954 until 1998, and a flotation plant upgraded the product for cosmetics markets. Near Murphy, North Carolina, small metamorphic-type deposits, which produced high-brightness talc for cosmetics and paints, were mined until the early 1980s. In Maryland and Arkansas, altered ultramafic deposits were mined for roofing and ceramics markets.

The mineralogy and chemistry of the commercial North American deposits produced today are summarized in Tables 1 and 2. Tables 3 and 4 present the mineralogy and chemistry of the major international talc ores.

Canada

Canada has deposits of talc in almost every province, but today production is limited to Ontario, with minor soapstone production in Quebec. Canadian production in 2000 was approximately 80,000 t. Major altered ultramafic deposits occur in Quebec, Ontario, Newfoundland, and British Columbia similar in nature to the Vermont deposits. Mining of soapstone, which was sawed for use in lining paper digesters, was a major business in the Broughton Area, dating back to World War I. Powder production began in the 1960s with a dry mill in Broughton and a flotation plant near St. Hyacinthe near the Vermont border. These operations have since shut down because of environmental and health (asbestiform contamination) concerns, and now only minor soapstone cutting for stove liners and sculpture carving continues.

Mining of the metamorphic deposits near Madoc in eastern Ontario, which dates from 1896, is now the only North American underground talc mine. The ore ranges from 30% to 80% talc, with dolomite, calcite, tremolite, and mica as the major impurities. It is white to gray in color and milled without beneficiation for applications in plastics and paints.

An altered, ultramafic deposit in Penh orwood Township in northeastern Ontario near Timmins was developed by open-pit mining in 1975, and a froth flotation plant was built adjacent to the mine. The ore is about 45% talc, with magnesite, magnetite, chlorite, and serpentine the impurities. It is now the major talc producer

in Canada and makes products for the paper, plastics, paint, and ceramic industries.

Central and South America

There is minor talc production in Mexico, Argentina, Peru, Colombia, and Uruguay. The major South American producer is Brazil, which mines about 300,000 tpy from deposits in Parana, Bahia, Sao Paulo, and Minas Gerais states. Parana is the major producing state with 200,000 tpy of talc from meta sedimentary deposits used primarily in the ceramic tile industry. The ore is 60% to 90% talc, with carbonate, chlorite, and quartz as the major impurities. It is gray to black in color but fires white because of a low iron content. In Bahia Province, a higher-purity white talc is produced by floating talc from a magnesite ore that is mined for steel refractories. Also in Bahia, some highly platy, mica-type talc ores are selectively mined in small quantities for the cosmetics market.

Europe

The major talc producer in Europe is Finland, with almost 500,000 t, followed by France (350,000 t), Italy (140,000 t), Austria (135,000 t), and Spain (100,000 t). There are major modified ultramafic deposits in northern Europe across northwestern Russia, Finland, Sweden, and Norway. The Finnish paper industry resorted to using these ores as fillers during World War II, when Cornish kaolin could not be obtained. A large paper company, United Paper Mills, developed the Lahnaslampi deposit in central Finland in 1969. A huge flotation facility was built nearby at Sotkamo, and production began to supply filler for papermaking. Two more major deposits at Horsmanaho and Lipasvaara, each with nearby flotation plants, were opened in 1977 and 1985, respectively. These are now consolidated under Mondo Minerals and produce talc primarily for paper coating, filling, and pitch control.

The deposits are all 55% to 65% talc with magnesite as the main impurity. Nickel sulfides occur in the Lahnaslampi ore and are recovered separately in the float circuit and sold as a by-product. The float plant upgrades the talc to ~95% purity with the balance being chlorite and magnesite.

In France, Talc de Luzenac has mined a talc-chlorite deposit of metasedimentary origin at the Trimouns mine in the Pyrenees in southern France for 100 years. The ore vein is 10 to 80 m thick, more than 1,500 km long, and dips at 20 to 60 degrees. The talc was formed when magnesium-rich fluids altered footwall silica and alumina-rich mica schists and gneisses. Chlorite, which makes up 30% to 60% of the ore, was formed in the micaceous and feldspathic footwall during magnesium enrichment, and the silica that was released during chloritization transformed the overlying dolomites into talc. Unmineralized dolomite forms the hanging wall of the deposit. Although the average ore is about 60% chlorite and 35% talc, through selective mining and hand sorting, grades with up to 90% talc are produced. Carbonates (0% to 3%), quartz (0% to 3%), and iron (0% to 2%) are the other impurities. Because of the elevation (2,500 m), mining is campaigned from May through October. After the ore is graded in lump form, it is transported by an overhead cableway down the side of the mountain to the mill located in the village of Luzenac. Paper and plastics are the major markets.

A very similar type of deposit comes from Austria's main producing mine in Rabenwald in the province of Styria. The talc-chlorite ore is mined in an open pit on the top of a mountain, and, after sorting, lump and screened ores are transported down the mountain to the mill in Oberfeitz by an overhead cableway. In the nearby village of Lassing, 10 underground talc miners in 1998 were killed when the mine was inundated with mud after a heavy rainfall. That mine is now closed.

Table 1. Typical mineralogy of North American talc ores

Mineral	Montana	Texas	Vermont	New York
Talc	95	80	60	30
Carbonates	2	15	35	<2
Tremolite		trace		60
Serpentine			trace	10

In Italy, IMI Fabi operates two large underground mines in the Sondria region of northern Italy. The ore, a metasedimentary type with high levels of dolomite and poor color, is used mainly in roofing and noncolor-sensitive plastics applications. Luzenac Val Chi sone operates another underground mine at Fontane, near Pinerolo in northwestern Italy. The ore, of metamorphic origin, is particularly platy and white and is prized in cosmetics and plastics. Luzenac also operates a small open-pit talc-chlorite deposit in Sardinia.

Spain

High-purity steatite talc is mined in Leon, and a low-grade ultramafic deposit is mined in Malaga. The Leon ore is from a high-grade metasedimentary deposit with good brightness and low iron content and is especially useful to the large Spanish ceramic tile industry. The Malaga deposit is used mainly in roofing and agricultural applications.

Other European Production

The other major producer in Europe is Norway. Mondo Minerals operates two talc-magnesite deposits (ultramafic origin) in

Altemark and Framfjord. Because of reserve issues, production has fallen significantly in recent years. The ore is mined at plants in Norway, England, and the Netherlands and sold primarily for industrial paint applications. Other small ultramafic deposits are mined in Sweden, the Shetland Islands, and Karelya in western Russia. A quite famous but small, high-purity steatite-grade talc deposit was mined at Gopfersgrun in Bavaria until 2002. The first machinable steatite used by industry was from this deposit, and the first synthetic steatite composition was produced by Thurneaur in 1932 with talc powder from this ore.

Africa

Relatively little talc is produced in Africa, with Egypt, Morocco, and South Africa having the only meaningful amounts of production. Egypt has deposits of both ultramafic and metamorphic origin in the southeastern deserts in the Precambrian metamorphic rocks of the Nubian-Arabian shield. Production has tended to be intermittent because of logistical, economic, and ownership issues. Some high-quality, cosmetics-grade talcs are mined near Agadir in Morocco. South African production is from mainly lower-grade mafic deposits that are milled for low-value uses in rubber dusting, fertilizers, and putties.

Australia

In Australia, three relatively high-grade metasedimentary deposits are mined. In Western Australia, the large Three Springs mine is in a massive, finely crystalline, white, high-purity talc deposit that has been mined by open-pit methods since 1961. The ore body is approximately 500 m long by 350 m wide by 20 m thick and is cut by a series of diabase dikes. Most of the ore is exported in lump form to Japan and Europe for paper and ceramic applications. Luzenac purchased the Three Springs deposit from Western Mining in 2001.

Also in Western Australia, the Mt. Seabrook deposit is a smaller, macrocrystalline, high-purity talc deposit that was opened in 1971. Although operation has been intermittent because of ownership changes and its remote location, the ore is valued in cosmetics markets for its plateness. In southern Australia, the Mt. Fitton deposit is the main source of talc for the Australian domestic market. The talc occurs in narrow (1 to 5 m thick) veins in a dolomitic rock, and both high- and low-purity grades are produced and shipped to a mill in Adelaide.

Asia

Asia is both a major talc-producing and -consuming region. China is the world's largest producer and exporter with 1.7 Mt, while Japan (450,000 t) and South Korea (200,000 t) are major importers. India (450,000 t) is the other major producer with most talc consumed domestically (Roskill Information Services 1997; Harris 2001; Virta 2004).

China

China has approximately 120 working talc mines located in three provinces: Liaoning and Shandong in the north and Guangxi in the south. Almost all the talc is of metasedimentary origin, and much of it, especially in Liaoning and Guangxi, is of high purity and has high brightness. Ownership is distributed among a range of provincial, district, and local village governmental bodies with limited private ownership.

The Liaoning deposits formed as metasomatic replacements of magnesitic and dolomitic carbonates of the Late Proterozoic Liaohe-Dashiqiao Group. The carbonates are dominantly magnesite with some tremolitic deposits within dolomite and calc-silicate rocks. The rock orientation is east-north east. High-purity veins are gener-

ally podiform and sheared. Mined widths range from 2 to 15 m with strike lengths from 10 to 500 m. Deposits are mined both underground and in open pit. The ore is sorted in lump form at the mine or in nearby villages, and about 50% is exported to Japan, Taiwan, and Korea.

In Shandong, the deposits belong to the Late Proterozoic Jueten-Zhanggezhuang Group. The talc is formed by metasomatic replacement of magnesium carbonates. Most ore is mined underground in veins of 7 to 30 m in width, often extending for hundreds of meters. The ore is of lower grade (<85%) talc, with the balance being magnesium carbonate and dolomite. Most ore is milled and used locally in the paper and ceramic industries.

In Guangxi, the talc deposits belong to the Middle Proterozoic Banxi-Heong Group and are the largest, highest-purity veins of talc in China. The principal mines are located along a N30°E fracture zone within a belt 2 km wide by 8 km long. The host rock is an off-white dolomitic marble that is contorted into high-amplitude isoclinal folds.

The talc veins are concordant, lenticular bodies that average 5 m in thickness and are 200 m long. The veins widen to 80 m and have sharp but irregular contacts with the host marble. The ore is typically light green to gray and locally very white. Chlorite, dolomite, magnesite, and quartz are the main contaminants.

Almost all mining in Guangxi is in open pits. Most high-brightness ore is exported to Europe and the United States in lump form. Reserves of high-brightness talc and production have been reported as diminishing in recent years.

India

The major Indian reserves and production are in the state of Rajasthan where the Golcha Group is the dominant producer. Most deposits are of the metasedimentary type, mined by open-pit methods, and sorted and processed locally for the domestic market. Approximately 5% of production is exported to Europe, Southeast Asia, and western Africa.

Production of talc is limited elsewhere in Asia, with Korea, Japan, and Iran having significant deposits and some production. At one time, Korea was a major producer, but output has fallen because high-quality, low-cost ore is available from China.

TECHNOLOGY

Exploration

Despite the availability of many modern geophysical techniques, the most effective talc exploration techniques are traditional field diagnostic, sampling, and mapping methods. Although talc is physically weak, it is chemically very stable, and the presence of talc in outcrops and in the overlying soils is the best diagnostic tool. After the deposits are sampled and mapped, if the quality is acceptable, the deposit is drilled, the quality confirmed, and the reserve estimated.

The value of any talc deposit is a function of its color, purity, and location, along with the availability of appropriate markets. Nowhere is this more true than in Finland, where relatively low-purity and low-color ultramafic deposits were developed successfully to serve the local paper market and replace expensive imported kaolin.

Mining

Most talc is mined today by conventional open-pit, drill-and-blast, shovel-and-truck techniques. The major difference from conventional technology is that blasting is minimized to reduce breakage of soft talc ore, and all shovel work is accompanied by a high level of selectivity to minimize cross contamination of high- and low-grade material. Many producers analyze blast-hole cuttings

to delineate ore grades and select blast patterns accordingly. Shovel operators can select ore or waste by color or texture for different grades. Equipment such as 10-m³ shovels and 150-t trucks are common in North America and Europe, while 1-m³ shovels, 20-t trucks, and even hand-carried baskets are used in Asia and Brazil.

A typical western talc deposit is drilled on 30- to 50-m spacing, and the ore body is characterized by mineralogy, color, and chemistry. From this, the ore body is defined and a computer-aided mine plan is generated. Overburden is removed and stored elsewhere for eventual use in mine reclamation. Mining is typically done on 5- to 10-m benches. Before each blast, drill holes are analyzed and, if necessary, the shot is reconfigured to remove potential waste or segregate a better quality of ore. After the blast, the shovel operator will selectively scoop the rock into haul trucks and designate it as waste or as a low or high grade of ore.

Waste-to-ore ratios are often quite high, especially for massive steatite deposits. Typical values range from 5:15 for massive ores and 1:3 for the lower-purity ultramafic grades. Underground mining is now less common and is declining rapidly in importance. Pure talc is a very soft, noncompetent rock, which is often highly fractured, of varying thickness, and in steeply dipping bodies. Where veins are thin and the surrounding rock is competent, openhand mining is acceptable with limited timbering. In thicker veins, underhand mining is necessary; where the veins dip steeply, shrinkage stoping is used. Some low-grade deposits can be mined by room-and-pillar methods, for which equipment is much smaller, blasting and mucking much more selective, and waste-to-ore ratios much lower than in open-pit mining. Continuous miners can be used on softer high-grade veins.

Reclamation

In contrast to past practice, reclamation is now an integral part of all talc mining in developed countries. Waste piles are graded, covered with topsoil, seeded, and monitored for a return to natural vegetation. For both surface and underground mining, both surface and subsurface water flow is measured, monitored, analyzed, and if necessary treated to meet local and national discharge standards. Some pits are backfilled or converted to a beneficial long-term use, such as recreation.

Beneficiation

Two major types of ore beneficiation are used for talc: sorting for massive talc ores and froth flotation for ultramafic and lower-grade ores. The sorting technology includes hand sorting of lump ore, mechanized optical sorting of pebble-sized ore, and slide sorting of lump ore to separate talc from dolomite and other impurities. Hand sorting usually takes place in sheds at process plants. Screened ore (5 to 25 cm in size) is run across belts, and, if low grade, talc is picked from the ore; if high grade, waste is picked from the talc. A slide-sorting process to replace this function was patented by Cyprus Industrial Minerals (now Luzenac America) in 1988. Talc has a much lower coefficient of friction than dolomite or quartz, so when dropped on a rotating plate, talc will quickly slide off while the other ore will be carried around and removed by a scraper. This type of sorting is particularly useful for high-grade talc that occurs in narrow (<1 m) veins in a carbonate host rock.

Optical sorting processes usually require talc to be washed and screened into narrow pebble size (1–2 cm) range. A camera scans each particle as it falls through a testing zone, and then jets of air either remove ore (for low grade) or waste (for high grade). This type of sorting is suitable for higher-value products such as required for cosmetics or plastics applications.

An important factor in the sorting and color beneficiation technology is that blending of low- and high-color ore is not linear. If equal parts of an 80 and a 60 brightness ore are mixed, the color is not 70 but much closer to 60. Conversely, if a small fraction of high-brightness ore is sorted out of a low-brightness ore, the effect on the color of the remaining low-brightness ore is minimal.

Ore beneficiation by froth flotation is usable for almost any ore, but it is particularly useful for ores where the talc is intercalated with the waste, such as talc ores of ultramafic origin. Ore is crushed and then milled to liberation size, typically about 50% passing 325 mesh. It is slurried in water at about 25% solids, and a frother, such as methyl isobutyl carbinol, is added. It is then passed through two to five stages of flotation where the talc content is upgraded to >95% purity. Carbonates, quartz, chlorite, and tremolite are selectively removed by this process. If a problematic level of dark magnetic minerals is present, high-energy magnetic separation is used to remove them from the floated product. The concentrate is thickened, filtered, and flash dried. Some producers mill in conjunction with the drying process.

Analytical Techniques and Measurements

A tiny fraction of talc is sold in lump form for carving, machining, or decorative applications. A significant volume of Chinese, Australian, and U.S. production is exported in lump form to the consuming countries. The vast majority of the ore must be reduced to a powder for end use. The size needed ranges all the way from –10 mesh (top size 2.5 mm or 2,500 μm) to 1,250 mesh (top size 10 μm). The distribution of the particles, sometimes called the granulometry, is also important. Some applications require a narrow particle-size distribution and some a broad distribution. Finally, the shape of the particles is critical in some applications and is affected by the grinding method.

In describing milled products, a number of measurements are used, most notably median particle size and top size. Median particle size is most often measured by sedimentation techniques using an instrument called a sedigraph. The sedimentation technique assumes that all particles are spherical, which talc particles are not. A sedimenting talc platelet will behave like a much smaller sphere, skewing the reported distribution toward the fine end. The technique is generally used only for subsieve-size particles (100% finer than 100 mesh [150 μm]). The technique will give a full particle-size distribution and is accurate down to ~0.3 μm . The other major subsieve technique is laser particle size analysis with instruments made by a number of companies including Coulter, Alcatel, and Horiba. Unlike the sedimentation technique, the laser analyzer measures the long dimension of the talc platelet, and thus the distribution reported by the laser will be quite a bit larger than that by sedigraph.

For top-size measurement, sieving and Hegman drawdowns are used. Sieves of 40 to 325 mesh are common. The Hegman bar, also called the fineness-of-grind gauge, is a technique borrowed from the paint industry. A small quantity of talc powder is dispersed under high shear in a vegetable oil. A small portion of the talc in oil dispersion is placed on the Hegman bar, which has a very accurately machined groove with a depth of 100 μm at the top end and zero at the bottom. When the talc in oil dispersion is drawn down through the groove, the coarsest particles will show up somewhere in between, and the material is given a Hegman rating based on the largest particles in the sample. For instance, particles of 70 μm give a 3 Hegman, and particles of 25 μm would give a 6 Hegman.

Other critical properties that are measured include surface area, bulk density, and color. Surface area is measured by the Brunauer, Emmet, and Teller (BET) method. It consists of adsorbing

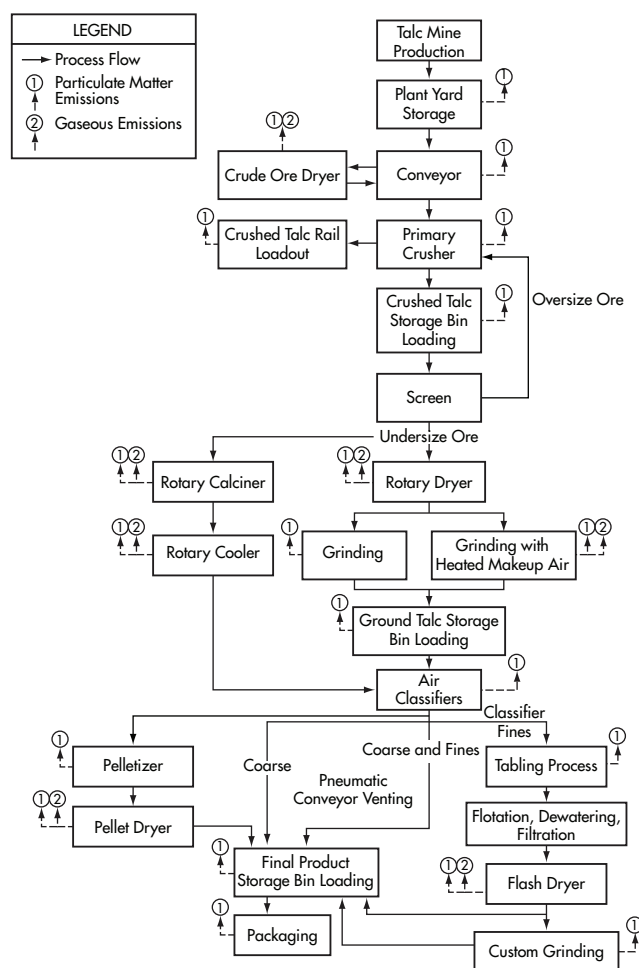

Figure 3. Flow scheme of a typical multiproduct talc plant

a monolayer of nitrogen on the surface of the sample and weighing it. Values vary from 1 m²/g for the coarsest, macrocrystalline products to 20 m²/g for the finest microcrystalline products. Bulk density is reported as either loose bulk density (LBD) or packed bulk density in grams per cubic centimeter. LBD is measured in a very simple piece of equipment called a Scott volumeter, in which the powder is cascaded over a series of glass plates into a 1 in.³ cube. After the cube fills, it is smoothed off and weighed. LBD values go from 1 to 1.2 gm/cc for coarse roofing products to <0.15 g/cc for the finest paint and plastic grades. LBD strongly correlates with median particle size and in many plants is used as a primary control parameter because it is quicker to run than a median particle size.

The science of color measurement as it impacts talc is quite complex and constantly evolving. Most producers measure powder color, which is achieved by pressing the powder into a pellet at standard conditions (3 bar pressure) and then measuring the color and brightness on the surface. There are a wide variety of measurement systems. The most commonly used is the General Electric brightness (GEB) method. GEB is measured on a simple scale of 0 to 100 on a brightness tester. Products vary from about 60, for low talc content, coarse products, to 96, for the finest, whitest talc products. Almost all ways, as talc products are milled finer, dry brightness improves.

The Hunter L-a-b scale measures color on three scales: *L* ranges from 0 to 100 on a white/black scale; *a* from red to green on a similar scale; and *b* from blue to yellow. A typical talc product with a GEB of 80 might have an *L* value of 86, an *a* value of 0.5, and a *b* value of 3. The *b* value, sometimes called *tint*, is the most critical as it is often reflective of iron staining. A lower *b* value is almost always better.

The powder brightness does not always reflect how the product performs in an end use. In plastics, for instance, the brightness of talc is typically lowered significantly as the talc surface is wet out by resin, which changes the optical image. To measure this, the powder is wet out in mineral oil and the color measured on the paste. In paint, the color is affected by hiding or opacity characteristics. In this application, platy talc, despite having lower powder color, is usually superior. This is measured by preparing a thin film over a black and white surface.

The other major analyses involve mineralogy and chemistry of the ore and products. In its simplest form, talc mineralogy is estimated from LOI data. The pure mineral talc loses its (4.75%) water of crystallization at 960°C. Thus the closer the 1,000°C LOI is to this, the purer the talc. If the major impurity such as dolomite or magnesite is known, the purity can be accurately estimated.

Mineralogy is measured more accurately by x-ray diffraction (XRD) techniques. An x-ray beam is sent through a pressed sample of the powder, and the beam is scattered at a specific angle by each mineral present. The location and intensity of that scattered beam is characteristic of the mineral and its level in the sample. Talc, chlorite, carbonates, asbestiform minerals, and quartz are readily identified and quantified down to concentrations of approximately 0.1% (1,000 ppm) by this technique.

A method to quantify the crystalline nature of talc was proposed by Holland and Murtagh (2000). They measured the intensity of the 004 and 020 XRD peaks and combined them in an equation (*I* represents beam intensity):

$$MI = I_{004} / (I_{004} + 2 I_{020}) \quad (1)$$

Their morphology index (MI) varied from 0.98 for the more macrocrystalline and platy Vermont talc to 0.45 for the microcrystalline Montana ores.

Chemistry is determined by either x-ray fluorescence (XRF) techniques or by more detailed wet chemistry techniques, such as inductively coupled plasma (ICP) and atomic adsorption (AA). XRF, done on a pressed powder sample, is accurate for silica, magnesium, calcium, iron, and aluminum down to perhaps 0.2%. The wet chemistry techniques are much more accurate but require that the samples be digested in a very strong acid, like aqua regia or hydrofluoric acid, before they are run through the ICP or AA instruments. This makes the technique much more expensive and time consuming.

Talc Milling

Talc is an extremely soft mineral and generally very easy to mill or to reduce in particle size, although the aspect ratio or platy nature of the talc can complicate matters. Preserving that aspect ratio is difficult in some milling processes, and a fine talc platelet is very difficult to handle and “manage” in an air stream, where almost all talc milling occurs. Very little wet milling is used.

If the ore is wet, the process will typically start with drying (Figure 3). Direct-fired rotary dryers are the most common. The coarsest talc products can be produced by crushers run in closed circuit with vibrating screens. Roofing products are produced in this fashion by running crusher discharge over a 35-mesh screen.

The most common milling machine in the talc industry is the ring roller mill, with the Raymond roller mill being the most popular type (Figure 4). In this mill, ore up to 50 mm in size is swept into a grinding zone between a set of rotating rolls that mill the talc between them and a horizontal ring. The fine product is swept out of the milling zone up to an air separation zone. Here a set of horizontal blades, called a whizzer, creates an airflow in a horizontal direction to the sweep air and forces the coarse particles out to the side and back down the circumference of the cylinder into the grinding zone. The fine product continues with the sweep air and is removed by centrifugal action in a cyclone. The air is recirculated with a large fan back into the grinding zone. A slipstream of air is pulled off after the fan into a dust collector. This keeps the whole system at a slight negative pressure and removes fines that are too fine for the cyclone to remove.

Roller mills are effective devices for milling softer (up to 3.5 Mohs hardness) materials down to 325 mesh top size (44 μm). They appear to preserve the aspect ratio and, if heat is applied, have the capability to do limited drying of wet feed. The primary control mechanism on the mill is the whizzer speed, with a higher speed giving a finer top size and a finer median particle size.

Newer mills use the more-sophisticated cage classifiers in place of the whizzer, which is not an efficient separation device. Cage classifiers require a higher pressure drop and usually a bigger fan but will enhance both throughput and top-size control. Products as fine as 5 Hegman can be made with enhanced classifier systems. Some producers use ball mills in closed circuit with air classifiers, especially for harder tremolitic talc or ore with high carbonate content.

To mill from a 325 mesh to a 6 Hegman, the most efficient machines are hammer mills with built-in classifiers, such as the Raymond vertical mill or the Hosokawa Micron air classifying mill, or ACM. The ACM is a compact hammer mill with an integral highly efficient cage classifier. The hammers are mounted on a plate in a cylindrical housing, and the rotation forces the particles to impact a serrated liner. They are then air-swept into the cage classifier zone where the coarse are knocked back and the fines are sent on to collection in a baghouse. The ACM can accept feed up to approximately 6 mm. The primary control mechanism in the ACM is classifier speed, with a higher speed giving a finer top size and a smaller median particle size.

For ultrafine grinding, often called *micronizing*, fluid energy mills are used. In this process, high-pressure (>10 bar) air or steam is expanded through nozzles into a grinding chamber. In some of these, the grinding chamber is a doughnut-shaped system, and the high-speed air flowing around the chamber in a centrifugal motion causes the powder to grind against itself. In the Aljet type, the fine product is taken off on a slipstream on the inside of the doughnut. In the Alpine type, the grinding is done by streams of opposing nozzles that inject pressurized air and powder into the base of a cylinder (Figure 5). The fines are taken by the milling air into the classification zone on the top of the cylinder where multiple cage classifiers reject coarse particles back into the mill. Product from all these systems are collected in baghouse filters, with care being taken to ensure that any cooling does not approach the dew point of the steam effluent.

Fluid energy mills are effective for milling from approximately 4 down to 7 Hegman top-size products. At the same top size, they will give a much finer median particle size than the ACM, and the centrifugal-type mills are believed to be better delaminating devices than the ACM.

The primary control mechanism in fluid mills is the integral or external classifier speed, with a higher speed giving a finer product. For mills without a classifier, the product can be made finer with a higher fluid-to-talc ratio or a higher fluid pressure.

Size Classification

The separation of products by particle size is just as critical a part of process technology as milling and, in most cases, is integrated into the milling circuit.

Screens are excellent absolute size separation devices, but their capacity and efficiency decline rapidly with finer meshes, and they are subject to rapid blinding and high maintenance with fine powders, platy materials, and agglomerates. In general, conventional screens are effective for separation of talc powders down to about 60 mesh. Below this, the powders agglomerate and blind the screens. For scalping-type applications (<0.5% oversize), air-swept screens can be used for powders down to 100 μm .

Air classifiers are devices in which a stream of air that contains fine particles (usually <100 mesh) is subjected to a velocity perpendicular to the direction of flow. This will cause the coarse particle to be deflected, allowing the fine particles to pass through. Two types of devices are used to create the perpendicular flow—blades (sometimes called whizzers) and cages that have a fanlike design. The latter are much more efficient, especially at fine particle sizes, but have higher pressure drop, lower capacity, and more potential problems. Typically the flow is upward, and the cage or whizzer is mounted vertically. When the separation points get finer (<20 μm), however, it is often advantageous to mount the unit horizontally.

Classifiers do not make a clean cut, and a platy particle behaves like a much smaller sphere. In addition, there are problems with bypassing, dispersion, and airflow control. In the most sophisticated units, all the accepted (fine) particles are forced through the vanes of the cage and exit through a hollow shaft on which the cage rotates.

The primary control parameter is the speed of the whizzer or cage, but other variables like airflow, air-to-solids ratio, and particle surface energy have significant effects. For any classifier, the higher the air-to-solids ratio, the better the classifier will work. But the operating cost is higher and the capacity is proportionally lower. Higher surface energy will have a detrimental effect in encouraging agglomeration, and this energy is an inevitable by-product of the milling process.

Densification and Compaction

The fluffy nature and low bulk density of fine talc products makes packaging and shipping difficult and expensive. To overcome this, producers use de-aeration and agglomeration technology to increase the bulk density of fine products.

The standard de-aeration technology uses a Carman densifier to pull air out of powders. The powder is transferred through a horizontal screw, which is surrounded by a filter cloth. A vacuum is pulled on the outside of the cloth, increasing the bulk density of a fine product by more than 100%, from 0.15 to 0.3 g/cc. The process has little effect on the talc itself as the powder reflows with minimal agitation. It does allow the product to be packaged in smaller sacks or to get 100% more talc in a regular sack.

In compaction the fine talc is wetted with about 20% water in a continuous mixer, and this paste is forced through a circular die to form pellets. These pellets are then dried to ~2% moisture for paper applications and <0.5% moisture for plastic and rubber. Bulk density is increased from 0.15 to 1 g/cc for fine products.

Other Processing Technology

A limited amount of talc is surface treated to improve its performance in specific applications such as plastics, rubber, and cosmetics. Amino-silane, polyethylene glycol, and stearates are some of the materials used. In general, the level of coating on talc products is rel-

atively low, in many cases less than 1%. This is in contrast to carbonates, where stearate coatings reach 3 wt % for ultrafine products.

A major development, especially in northern Europe, is the delivery of fine talc to paper mills in slurry form for use in paper coating. Fine talc, which has high surface energy and hydrophobicity and a platy structure, is difficult to wet in water and extremely difficult to make into a stable, high-solids slurry. Nevertheless, close to 350,000 tpy are now produced in this form in Europe. The talc is dry milled and then made down into slurry using high-energy mixers and a proprietary package of dispersants and stabilizers. The slurries have solids content of 61% to 65% and a viscosity of ~200 centipoise. A limited amount of talc is also shipped for pitch-control applications in slurry form, but the solids content is much lower and no chemicals are used.

Packaging and Shipping

Talc products are shipped in super sacks (400 to 1,200 kg) and in paper bags (usually 25 kg), stacked on wooden pallets. Transportation to the customer is a significant portion of the total cost of talc products, averaging 25% to 30% of the cost and, in some cases, more than 50%.

Most talc products are now shipped by truck. The combination of faster, more-reliable delivery and lower costs for most customers continues to favor this mode. Rail is used for larger-volume bulk customers when the haul distance is more than 500 km. Most trucks will deliver coast to coast in 4 or 5 days while rail delivery will typically take 2 to 3 weeks.

Bulk trucks are very popular with customers, because the truck driver unloads the material with a compressor on the truck, in contrast to bulk railcars where the customer has to supply the compressor and unload the material. Most product is shipped directly to customers. Smaller customers typically purchase through chemical distributors, who buy the product from the talc mills and store it locally.

PRODUCT APPLICATIONS

The section that follows is not intended to be scientifically complete or to cover all the applications and potential applications in different industries, but is more heavily weighted to major applications, major developments, and technological changes that affect talc consumption. This section also attempts to evaluate talc's position in the market compared to competitive minerals and chemicals.

Almost all of the talc markets are mature and thus are characterized by limited growth (at or below gross domestic product [GDP] rates), customer consolidation, competitive substitution from other minerals, and downward pressure on prices. This is certainly true of the pulp and paper, paint, rubber, joint compound, putty, flooring, roofing, cosmetics, and agricultural markets. The exceptions are plastics and ceramics. Although plastics is a mature business, it is enjoying a growth spurt as talc-reinforced polypropylene replaces more expensive engineering polymers in automotive applications. New applications in ceramic pollution-control devices are also showing significant growth.

In most markets, talc competes with other minerals, such as calcium carbonate, kaolin, and silica. In some markets, however, most notably pitch control, talc competes with alternative pitch-control technologies, including dispersant and detackifying chemicals, periodic solvent washes, or improved processing procedures.

Another critical piece of the application picture is the usability of the talc product. In paper, for instance, although customers prefer slurry, producers find it more convenient to supply a dry product. In plastics, customers prefer a dense, dustless, easy-to-disperse pellet. Plastic compounders are now supplying concentrates of 70% to 80% talc in plastic resin.

Paper

Pitch Control

Beginning as an accidental development of Sierra Talc Company in the northwestern United States in the late 1950s, the pitch-control market has grown steadily to become the largest market for talc in North America today, consuming close to 160,000 t in 2000 (Table 5). The pitch-control market has consistently been dominated by Montana-based products, and although the talc has become coarser over the years, the market continues to accept microcrystalline products from Montana as the industry standard.

Wood is made up of three components—fiber, cellulose, and resins—that are liberated from each other in the pulping process. In thermomechanical pulping, the wood is broken apart by a combination of heat and energy, and all the components are left in the final pulp. In chemical pulping, a combination of mechanical, physical, and chemical separation processes are used to produce essentially pure fiber. It is in chemical pulping that talc works best, helping to produce a cleaner and more valuable fiber. Talc has also had good success in recycle mills, where previously used paper is repulped, and contaminants, such as ink and adhesives, are removed by physical means. In both cases, talc is used more or less as a scavenger for the residual oil droplets or resin particles that are left in the pulp. It prevents them from adsorbing on machine surfaces, screens, and felts, and the talc/contaminant mixture is retained in the pulp as an inert filler.

The mechanism by which talc works is not totally clear, except that it effectively sorbs on to the pitch, detackifies it, and limits its ability to deposit. Some of the mechanisms that appear viable are migration of the talc into the oil phase, the peptizing of pitch particles by the surfactant-like talc, the adsorbing of pitch onto the larger planar surfaces of talc, and the steric stabilization of the pitch dispersion by the talc. One or more of these mechanisms is likely to be effective in different situations.

Where talc is ineffective, as in thermomechanical pulp, the mechanism is clear. The anionic trash (lignin products) left in the pulp preferentially adsorb on the surface of talc and render it ineffective. Even 1,000 ppm of anionic surfactant will completely negate the ability of talc to work in this environment.

In earlier years, talc was added to the process in repulpable 50-lb bags. Talc producers, such as Cyprus, developed talc dispersion units (TDUs) that can take talc from a super sack or bin and produce a dilute (~5%) suspension of talc in water. Typical addition rates are 5 to 10 kg of talc per ton of pulp. The standard product for the application is a microcrystalline Montana talc product milled to a 3.5- μ m median particle size and a surface area of 13 m²/g.

The main competition for talc is from specialty chemical companies. Traditionally, these companies sold dispersants for this application, but dispersants sent the pitch to the waste treatment plant where it added to chemical oxygen demand (COD), whereas talc kept the pitch in the pulp. The specialty chemical companies have now revised their products and sell materials with trade names such as Surround and Detac, a competitive recognition of the peptizing and detackification properties of the talc product.

Paper Coating

The concept of talc as a paper-coating pigment was developed by the Finnish United Paper Mills and its subsidiary FinnMinerals in the early 1980s. Partially driven by a need to control the costs of imported English coating kaolin, the company found that talc significantly improves print quality and cuts down on core burst problems when used as a component of rotogravure grades of lightweight coated paper. Today, more than 300,000 t of talc are

Table 5. Talc usage by major market area, ktpy

Market Area	North America	Europe	Asia
Paper	195	605	1350
Plastics	160	280	170
Paint	150	155	105
Ceramics	130	150	90
Putties	120	90	50
Cosmetics	35	25	25

used for this purpose in Europe. North American coating talc use is minuscule because of the relative economics of talc and kaolin. In Europe, most kaolin is imported from the United States or Brazil and is more expensive than talc. In North America, high-quality delaminated kaolin is available from Georgia at half the price of talc.

The coating product used in Europe has a 2.5- μ m median particle size and 85 GEB and is sold in a highly stable 63% to 64% solids slurry. Most is produced in Finland from a macrocrystalline ore made by froth flotation and dry micronizing.

Paper Filling

Talc has been used in paper filling for more than 80 years, especially where it was inexpensive and where kaolin was not available locally, such as in southern Europe, China, Japan, and Finland. At one time, more than 1 Mtpy was probably consumed worldwide for this application. With the increase in alkaline pulping throughout the world, usage has declined, but the market still exists for certain grades in Europe, China, and Japan. The typical product is 99.9% –325 mesh, and 80 to 85 GEB. Because of its surface and larger particle size, talc has better retention in paper than kaolin, improves drainage and print properties, and generally makes a stronger and smoother sheet.

Little talc has been consumed in North America for this application since Georgia kaolin became plentiful and inexpensive in the 1930s. In the rest of the world, the application is declining because of the availability of less-expensive ground and precipitated calcium carbonate fillers.

Paints

Talc and other mineral pigments such as calcium carbonate have been used in coatings for more than 100 years. Initial use was based on local availability, acid solubility, and whiteness. Over time, talc has been recognized for its good anticorrosion and moisture barrier properties, weathering and antisetling properties in oil, hiding and color extension, and flattening properties. Today approximately 150,000 tpy are used in paint in both North America and Europe.

Basically, two grades are sold. The coarser 3 Hegman grades are used for general purpose extension in architectural (household) coatings and as a functional additive in alkyd primers and industrial coatings. Finer 5.5 to 6.5 Hegman grades are sold for flattening in alkyd coatings, barrier applications, and corrosion prevention in maintenance coatings; for pigment extension in color concentrates; and for viscosity build in gel coats. The coarser products represent 60% of the overall volume. Other than top size, the most important properties of a talc in coatings are color or brightness and its contribution toward the paint viscosity. The viscosity build property is loosely related to oil adsorption (ASTM D281), and a high or low value can be beneficial depending on the system employed.

Although most of the products sold are made from high-purity, platy ores, the tremolitic New York State talc and the natural

talc-carbonate ores are favored for certain applications because they have lower viscosity and better scrub resistance than pure talc. The 3 Hegman grades are made on roller mills or ball mills in closed circuit with air classifiers. The 6 Hegman grades are made on fluid energy mills and air classifying mills.

In water-based coatings, talc is a good spacer for prime pigments such as titanium dioxide; it reinforces the film, contributes to low shear rheology (antisetling), and helps to roughen the surface, which reduces gloss and promotes interlayer adhesion. In oil-based coatings, talc wets out easily, reinforces the film, reduces permeability, and has inherent corrosion-resistant properties. The gray epoxy paint on U.S. naval vessels is pigmented with mostly Montana talc and a little lampblack.

Talc competes with calcium carbonate, kaolin, and mica in the paint market. Although it is more expensive and generally not as bright as calcium carbonate or kaolin, it has better weathering and anticorrosion properties and a lower "b" value or yellowness than kaolin. Because of its higher cost, however, it is rarely used (only when its functional properties justify the extra expense) as an inert "filler." As the production of oil-based coatings continues to decrease, the paint market is relatively static for talc because the limited overall market growth just about compensates for the loss of talc share.

Plastics

Plastics is the fastest-growing market for talc in North America, with growth rates of more than 6% per year with close to 140,000 t consumed in 2000. The main application is reinforcing and nucleating polypropylene, especially for automotive uses. Lesser amounts are used as film antiblock additives and in engineering and thermoset polymers.

The polypropylene (PP) application is driven by a basic technology shift in automotive production. Talc-reinforced polypropylene replaces a number of more expensive and exotic engineering polymers, especially acrylonitrile butadiene styrene (ABS) and polyurethane in the interior panels and exterior bumpers of cars. The engineering polymers sell for \$2 to \$4/kg; polypropylene sells for \$0.7 to \$0.9/kg. But PP itself does not match the strength, heat resistance, dimensional stability, or molding properties of the more expensive polymers. PP is a semi-crystalline polymer, and talc surface has the ability to improve the crystallization rates to the point that dimensional stability is improved, mold shrinkage is reduced, and stiffness is improved. Fine talc is used at 2% to 10% concentration in large parts like bumpers for this purpose. Talc is also capable of reinforcing PP, increasing stiffness 150% at 30% to 40% loading. This property is used in interior panels and dashboards. Molded color is extremely critical in this application because the parts are color matched. Under the hood, black parts such as ducts and covers are also made from talc-reinforced PP. Here, heat resistance and long-term heat stability are critical. In the PP resin, 325-mesh talc products are used at 30% to 40% concentration.

The shift to PP has been driven by Japanese manufacturers, who have reduced the number of parts and the total cost of their cars by using this and other technologies over the last 10 years. As more Japanese auto companies have begun manufacturing in North America, they have been followed by Japanese compounders for talc-reinforced polymers. These compounders tend to use the finest and whitest talc products, and their technology is now being transferred to U.S.-based companies.

Talc-reinforced products are also used in appliances such as washing machines and refrigerators, in plastic trays for fast-food restaurants, and in fire-retardant applications where talc will increase low shear viscosity and prevent the hot plastic from dripping.

In polyethylene film, talc at about 0.5% will act as an anti-block. It detackifies the resin so that adjacent layers of film will not stick together, but it will not negatively affect film clarity or strength. Talc is also used to nucleate and reinforce nylon and polyester for electrical and packaging applications.

A major handicap to talc use in polymers is the difficulty of mixing it into resin. Most of this is done by specialty compounders, who use high-energy extruders or rubber mixers. These compounders now generally sell their products as 40% to 80% talc in resin concentrates to the manufacturers who actually mold the parts. These master batches are mixed with virgin plastic pellets and extruded or molded at the proper talc loading, usually less than 30%.

Even though talc has a major position in plastics and its use will continue to grow as domestic auto producers switch to PP, it is losing market share to calcium carbonate, especially stearate-coated fine 1- to 3- μ m products, elsewhere in the plastics market. Carbonates provide impact resistance but little stiffness. They work well in applications where the finished product is low in price and disposable, such as plastic grocery bags. Carbonates have always dominated the thermoset portion of the market but now are growing dramatically in film, polyvinyl chloride (PVC), and general construction products. With the exception of nylon, kaolin finds little use because of its surface properties. It does not mix well with polymers and will degrade the polymer during compounding.

Talc is also widely used in a related industry: rubber. Micronized talc is used as a reinforcing agent in mechanical rubber goods such as hoses and belts and as an insulating agent in wire and cable coatings. It will also function as a process aid in extruded rubber profiles such as the seals on automobile doors and windows.

Coarser 325-mesh talc is used as a dusting agent on molded products such as tires and elastomeric thread. These markets, however, are declining.

Ceramics

Ceramics remains a major use for talc in the Americas, especially in the floor and wall tile industries of the United States, Mexico, and Brazil. At one time, tile consumed 50% of U.S. talc production, at more than 600,000 tpy. The tremolitic and white firing talcs from Death Valley in California and from New York, and later the white-firing ore from west Texas, were particularly preferred. The typical body was 60% talc and 40% ball clay, pressed and slow fired to form a porous bisque, which was then glazed and refired to make the final tile. Until the 1970s, when new glazes were developed, this was the only way to make a tile on which the glaze did not crack.

This technology is no longer economically viable. Most tile products today are either single-body porcelain tiles or pressed, glazed, and fired only once. Feldspar, silica, and ball clay are the major body components, with talc reduced to the role of a fluxing additive to reduce porosity and increase strength. As such, it is used at levels of 3% to 7% in the body. This is still substantial, as the ceramic tile industry is very large and growing at more than 5% per year.

In tile applications, talc purity is not critical, but low iron content (<0.5%) is. Most of the product used in the United States and Mexico still comes from west Texas, with minor amounts from New York. Many producers purchase lump ore and co-mill the talc with feldspar and other ingredients. Where powder is used, coarse products with 99% passing 100 mesh are typical.

A major growth market for talc is the honeycomb cordierite substrates used in automotive catalytic converters and diesel particulate filters. As clean air regulations become more stringent and extend to include light- and heavy-duty trucks, this market is

expected to grow dramatically. Cordierite is a magnesium aluminum silicate, which is formed at 1,350°C by firing a mixture of talc (35%), kaolin (40%), and alumina (15%). Cordierite has an extremely low coefficient of thermal expansion, which allows it to go through thousands of heating and cooling cycles and maintain its mechanical strength. This market is dominated by two suppliers: Corning of the United States and NGK of Japan. High-quality talc from North America is used worldwide in this application.

The traditional electrical porcelain markets in synthetic steatite and cordierite are declining rapidly. Synthetic steatite can be made by pressing or extruding a mixture of 80% talc, 10% plastic kaolin, and 10% feldspar and firing to 1,250°C. Although synthetic steatite was used in high-temperature and high-frequency insulators in the automotive industry and in appliances, today better plastic products are replacing the synthetic steatite in lower-voltage applications. Other markets in whitewares and kiln furniture are declining because of technological changes.

Talc does not compete with any other mineral in ceramics.

Construction Products

This area, which includes roofing shingles, vinyl flooring, joint compounds, caulking compounds, and automotive body patching, is a huge market for minerals, most of which are low in price. More than 100,000 tpy of talc are sold into this market, most of it low brightness and low purity. The major mineral used in this market is limestone, with close to 10 Mt utilized each year.

In the manufacture of asphalt roofing shingles, coarse platy talc is applied to the back of the shingle to prevent sticking during the manufacturing process, storage, and shipping. A platy talc with 100% passing a 30-mesh sieve and <40% passing a 200-mesh sieve is preferred. Talc competes with sand and coal slag in this application. In the manufacture of rubberized asphalt sheet roofing, 200-mesh roller-milled talc can be used as a filler to reduce the loss of lighter hydrocarbons in the asphalt and improve weathering. Talc also competes with limestone in this market.

In vinyl flooring, talc is used in the felt backing to prevent cracking when the felt is bent during installation. In sheetrock joint compounds, 200-mesh talc is added to build body, prevent cracking, and promote sanding properties. Such compounds are typically 85% carbonate, 10% talc, and 5% resin and other additives.

In caulking compounds, talc and synthetic silica are used together to obtain the right combination of flow (low high-shear viscosity) and sag resistance (high low-shear viscosity). Both coarse and fine products are used at 5% to 25% levels in the formula. In automotive body patch, talc makes up about 45% of the formula, with polyester resin as the balance. Talc builds viscosity and creaminess and allows for good sanding after the polyester cures. The mixed talc-carbonate Vermont ores milled to 200 mesh are preferred.

Cosmetics and Pharmaceuticals

Baby and body powders are one of the more traditional and best-known uses for talc, but it is a market in continuing decline. In developing countries, talc is used extensively in bar soaps and detergent powders, but elsewhere body powders are being replaced by stick and spray deodorants, and many powders are now starch or starch-talc blends. About 35,000 tpy are used in this area, and, although the average selling price is one of the highest in all industry segments, both pricing and volume continue to decline.

The major products are pure 200-mesh roller-milled talc made to tight chemical, microbiological, and loose bulk-density specifications. The market has now gone primarily to high (>0.5 g/cc) loose bulk-density products that flow and fill better and are sold pri-

marily as superstore brands. Only a few brand name marketers such as Johnson & Johnson participate now, and their share continues to decline. Elsewhere, 200-mesh talc is also used as a minor ingredient in "speed-stick" type underarm deodorants, whereas finer talc is used in pressed powders, creams and lotions, and chewing gum.

The market for talc in cosmetics and personal care is still very much under a cloud because of potential action from the National Toxicology Program (NTP) on the health aspects of talc.

Other Applications

Agricultural Products

Talc has traditionally been used as a carrier for all kinds of pesticides, herbicides, fungicides, and crop dusts, although these uses have declined except for seed potato dusts. It is also used as a parting agent for granular fertilizers and ammonium nitrate, but this application has been replaced largely by oil-based soaps. Talc is used as a flow improver for hygroscopic feeds like soy meal, as a process aid in certain types of olive oil production, and as a lubricant in many seeder machines, where it competes with graphite.

Friction Products

Coarse talc is used in the manufacture of brake pads, primarily to adjust the coefficient of friction in conjunction with graphite. Talc is also used as a lubricant in some dry lube and grease formulations.

Wastewater Treatment

Talc can act as a flocculant for the mixed bacteria in biological oxidation systems that are widely used to remove soluble organics from both municipal and industrial wastewater or as an absorber of oil and grease in primary treatment. The application has been patented by Luzenac and commercialized in Europe.

HEALTH AND SAFETY

In the last 30 years, health and safety concerns have become a major issue in the talc industry. The initial problems, dating to the 1970s, were related to asbestiform fibers, but in the last decade, they have extended to crystalline silica and even the talc mineral itself.

Talc powder is considered a nuisance dust and has a threshold limit value (TLV) for an 8-hr exposure of 2 mg/m³. All manufacturers now require workers handling talc powders to wear dust masks if the exposure is close to this level.

The geology of talc makes it apparent that certain types of talc deposits will be associated with asbestiform fibers (metamorphic and ultramafic types). The major commercial type, metasedimentary, is associated with silica. When a asbestos carcinogenicity became an issue in the 1970s, much of the talc-producing industry was affected. Fibrous tremolite was recognized as being a carcinogen and tremolite was a component of talc produced in California, Georgia, New York, and North Carolina. All these deposits, with the exception of New York, were shut down. Tremolite occurs in two forms—blocky and fibrous—and R.T. Vanderbilt, the major New York producer, challenged the regulations that treated all tremolite as a carcinogen. In 1994, the federal government agreed and subsequently regulates only the fibrous form.

Although the legal labeling requirement is 1,000 ppm of asbestiform mineral, the analytical techniques for analyzing asbestos have now improved, allowing for its detection by electron microscopy at 10 ppm. Luzenac shut down a mine in Quebec in April 2001 when asbestos fibers were detected at well below the legal limit.

In 1985, respirable crystalline silica was named a probable human carcinogen by the International Agency for Research on

Table 6. World talc production and trade statistics, ktpy

Country	Production	Exports	Imports
China	1,700	950	~2
United States	817	180	250

Cancer, triggering labeling requirements required by U.S. government regulations. *Respirable* is basically defined as the 0.5- to 10- μ m particle size range. These regulations require all products containing more than 1,000 ppm (0.1%) of a known carcinogen to be labeled. Although almost all talc products exceed this 1,000 ppm of total crystalline silica, most of the silica is not in the respirable range.

Many producers also maintain that there is a long history of safe talc use, and that because these mixtures of talc and silica have been found safe in extensive use tests, there is no need to label. The Occupational Safety and Health Administration of the U.S. government has now accepted this logic.

More recently, a number of epidemiological studies have shown a weak association between perineal talc use and ovarian cancer. There is a strong difference of opinion within the scientific and medical communities as to the validity of these studies, both because the association is weak and because no fundamental scientific basis exists for the association. In 1998, the NTP placed talc on a review list for possible listing as a cause of ovarian cancer. After peer review and public comment, the NTP panel of experts voted 7 to 3 in late 2000 not to list talc in this category. Nevertheless, the debate continues, and much fundamental and applied science, as well as political pressure, is now being applied by both sides. In 2004, NTP announced that it will reexamine the issue and that review is under way.

COMMERCIAL ASPECTS

Worldwide, talc is approximately an \$800 million per year business at the finished product level. Some 5.0 Mt of product are sold at an average of \$160/t. Virta (2004) estimates the value of U.S. production (0.857 Mt) at \$23.3 million at the ore level, at an average of \$27.18/t. On a worldwide basis, this appears to be low, and where ore is traded, statistics suggest a value of ~\$65/t f.o.b. mine.

Table 6 summarizes world production. The major producer, China, has a very diverse ownership, mostly state and local governments. Most exported ore is handled by traders such as Dailen Haicheng Talc Trading, Gongrong International, Minmet, and South

China Trading Company. Well-known producers are Liaoning Ahai Talc with an output of 180,000 tpy, Haicheng Beihai Minerals (100,000 tpy), and Pingdu talc mine (100,000 tpy).

Worldwide, the major private producer is the Luzenac group of Rio Tinto plc, which produces approximately 450,000 tpy in the United States and Canada; 600,000 tpy in France, Austria, Spain, Italy, and Belgium; and 150,000 tpy in Australia. Other major producers and their production totals are

- Mondo Minerals: 550,000 tpy in Finland, the Netherlands, and Norway
- Golcha Group: 250,000 tpy in India
- Costalco: 200,000 tpy in Brazil
- Barretts Minerals of the United States (subsidiary of Minerals Technology): 150,000 tpy in Indiana, New York, and Ohio
- Gouverneur Talc (subsidiary of R.T. Vanderbilt): ~120,000 tpy in New York
- IMI Fabi: ~120,000 tpy in Italy and the United States
- Wold Resources; ~120,000 tpy in west Texas.

Over the past 20 years, there has been a major consolidation of production both in the United States and worldwide. In 1982, the United States had 14 producers with 26 active mines, and at least 5 were underground. Today, there are only seven producers and 9 mines, all open pit. Production in formerly major producing states such as California and Georgia has almost ceased because of environmental and economic factors. There is less production of lower grades such as the higher tremolite and carbonate products and much higher production of the higher-purity Montana, Chinese, and floated grades.

International trade in talc is very large, with some producers such as China, Australia, and Austria exporting most of their talc and some consumers such as Japan, South Korea, and Germany importing to meet their needs. In the Far East, China and Australia are the major exporters, and Japan, South Korea, and Taiwan are the major importers. Most imports are ore, which is then milled domestically for paper and plastics markets.

In Europe, the major exporters are France, Finland, Austria, Italy, the Netherlands, and Belgium. The major importers are Germany, the Netherlands, the United Kingdom, and Belgium. In contrast to Asia, most trade is in finished goods, except for Belgium and the Netherlands, which import mostly ore.

In the Americas, there is significant cross-border trade between the United States and Canada in finished talc products, and a significant export of ore and finished products from the United States to Mexico, primarily from west Texas to Monterrey, Mexico, for ceramics. The United States is a major importer of ore, especially from China, which is milled in the United States for plastics and cosmetics markets.

This trade is now manifested in an increasing reliance in Europe and the United States on talc ore imports from Asia and Australia—both now net importers of talc. Along with this trend is the growth of mineral processors, which mill and market purchased and mostly imported ore. This growth has been facilitated by two factors. First, significant quantities of high-quality ore are available at reasonable prices, mainly from China and to a lesser degree from Australia and India. Second, the sale of talc requires a high degree of product application expertise and marketing acumen, skills that are not always present in mining companies.

The pricing environment for talc has been extremely poor over the last 10 years. There has been an excess of both ore production and milling capacity, and pricing of equivalent products has either not kept pace with inflation or declined in real terms. Although the

average price for talc product has increased, this is somewhat deceiving, as lower-cost materials such as silica sand and calcium carbonate have displaced talc in lower-value applications and left talc with a smaller number of higher-value-added markets. The poor state of the major consuming markets, especially paper and construction products, has not helped. Industries such as paper, ceramics, roofing, and paint have suffered from excess capacity, poor pricing, consolidations, and shutdowns in the same time frame.

Overall production of talc worldwide appears to be falling significantly. Production was estimated to be 7 Mt in 1990, 6 Mt in 1995, and 5 Mt in 2000. This appears to be driven by less demand for lower-grade tremolitic and carbonate ores in construction markets along with a conversion of European and Asian paper-filling markets from talc to calcium carbonate.

The industry has also struggled with environmental and health issues, and the legal problems experienced by asbestos producers and users cast a heavy shadow over investment and business prospects.

FUTURE TRENDS

These trends—increases in demand for higher-purity products in plastics and paper coating, decline in demand for construction and paper filling, and consolidation and continued environmental concerns—are likely to continue. Future talc applications will be concentrated in the high end of the value chain, where the price is more elastic. Volumes are unlikely to grow and may continue to decline. Revenue growth, however, may be more positive because of the growth in higher-value applications.

The prospects on the pricing front appear better. Chinese production is declining, especially in the higher-purity bright ores. Ocean freight rates from China to Europe and North America have increased significantly in recent years. The quality of the available lower-priced carbonate and tremolitic ores in Europe and the United States is not sufficient for the paper coating and plastics market.

Unless a major new low-cost source of high-quality ore is developed, then, pricing should remain firm and at least keep pace with inflation. Of course, technology changes can always have an impact on demand. The construction market for talc has largely been lost to lower-priced carbonates, kaolin, and silica sand. If more economic alternatives to talc are found in paper coating and plastics, demand will continue to decline. The challenge remains for talc producers to develop new applications for their product, but this effort has declined significantly in the past decade with consolidation and lower profitability.

The environmental climate for talc mining is also challenging. Permitting, even for dry milling and smaller mining operations typical of talc, is very difficult. With some operations located in environmentally sensitive locations, existing facilities are subject to a high degree of scrutiny. The health concerns with talc and its associated minerals are likely to become more acute. Although existing producers are committed to ensuring that sound science is applied to the issue, health issues are an emotional subject and difficult to deal with in a public forum.

Generally, then, the future for talc is at best cloudy, with significant challenges to be addressed for the remaining producers. The key competitors will not be from within the community of talc producers and marketers but from the minerals or technologies competing for a position in the portfolio of available applications.

Titanium

Philip Murphy and Louise Frick

INTRODUCTION

Titanium occurs in the earth's crust in two predominant commercial minerals, ilmenite and rutile. Ilmenite, occasionally known as titanoferrite, was named in 1827 after a locality in the Ilmen Mountains, Southern Urals, Russia. Ilmenite is a common accessory mineral in many igneous and metamorphic rocks and forms a solid solution with hematite above 600°C. Below 600 °C, ilmenite commonly occurs with hematite. The name for rutile originates from the Latin *rutilis*, in reference to the red color that is observed when the mineral is viewed in transmitted light. Rutile is a common accessory mineral in many igneous rocks and some metamorphic rocks.

The principal application for titanium minerals is as a feedstock for the manufacture of titanium dioxide (TiO₂) pigment, which accounts for more than 90% of global titanium mineral consumption. As the most widely used white pigment, TiO₂ is employed mainly for its opacifying properties in a wide variety of consumer goods such as paint, paper, and plastics. The titanium feedstock industry as a whole, all the way down to the exploitation of titanium mineral deposits, is therefore predominantly driven by trends in the TiO₂ pigment industry and the specific technical requirements of TiO₂ pigment manufacturing processes.

PRODUCTION AND TRADE; RESOURCES AND RESERVES

Titanium Mineral Supply

Titanium feedstocks for the production of TiO₂ pigment, titanium metal, welding electrode flux, and other, minor uses include the minerals ilmenite, rutile, and leucoxene, and the beneficiated products synthetic rutile and titanium slag. Feedstocks are classified according to their suitability for either chloride or sulfate processing in the TiO₂ pigment industry, and are categorized as follows.

Chloride-grade feedstocks:

- Chloride-grade ilmenite, typically 60% TiO₂
- Leucoxene, typically 75% to 91% TiO₂
- Rutile, typically 95% TiO₂
- Chloride-grade slag, typically 86% TiO₂
- Upgraded slag (UGS), typically 95% TiO₂
- Synthetic rutile (SR), typically 90% to 93% TiO₂

Sulfate-grade feedstocks:

- Sulfate-grade ilmenite, typically 44% to 57% TiO₂
- Sulfate-grade slag, typically 75% to 80% TiO₂

Figure 1. TiO₂ feedstock production by country (2003)

Table 1. World titanium mineral production in 2003 by country and product, in thousand TiO₂ units*

Country	Ilmenite for Pigment	Leucoxene	Rutile	Synthetic Rutile	Slag	% of World Supply
Australia	504	73	160	615	0	27
Canada	0	0	0	0	677	13
India	163	0	14	66	0	5
Malaysia	51	0	0	24	0	1
Norway	247	0	0	0	143	8
South Africa	27	0	102	0	790	18
United States	295	31	25	94	0	9
Other	846	1	64	0	30	19
Total	2,133	105	364	798	1,640	100

* TiO₂ units are calculated as ton of feedstock multiplied by the proportion of TiO₂ contained.

Total titanium feedstock production in 2004 is estimated at 5.14 million contained TiO₂ units, the standard measure for comparison of feedstocks, which is calculated as a ton of feedstock multiplied by the proportion of TiO₂ contained. This compares with 5.04 million contained units in 2003.

Australia remains the world's largest producer, providing approximately 27% of total supply in 2003 (Figure 1, Table 1). Australia is the leading producer of SR, and a major supplier of

Figure 2. Global titanium feedstock supply by product (1980–2003), in thousands TiO_2 units

sulfate- and chloride-grade ilmenites. South Africa was the second largest feedstock producer in 2003, supplying mainly chloride-grade slag. The other significant titanium feedstock producing countries are Canada, the United States, and Norway.

Ownership in the titanium feedstock industry is highly concentrated, with the top three producers responsible for 47% of global feedstock production in 2003 and the top nine producers accounting for 75% of world output. Iluka Resources Limited (including its 51%-owned Consolidated Rutile Limited subsidiary) headed the producer rankings in 2003 with total production of 992,000 TiO_2 units, a market share of 20%. QIT-Ferret Titane Inc. (QIT) was the second largest producer with a market share of 14%, closely followed by Richards Bay Minerals with 13%, which was unusually low because of temporary production cutbacks.

Titanium slag has dominated feedstock production since 1990, when it first surpassed ilmenite as the major feedstock category (Figure 2). In 2003, slag (including chloride slag, sulfate slag, and upgraded slag) accounted for 33% of titanium feedstock production. Ilmenite (both chloride and sulfate grades) accounted for 42% of the total because of the rapid expansion in China. Sulfate ilmenite is the largest single feedstock category, accounting for 30% of total production.

GEOLOGY

Mineralogy

The chemical formula of ilmenite is FeTiO_3 , often expressed as $\text{FeO} \cdot \text{TiO}_2$. The composition is 36.8% iron, 31.6% titanium, and 31.6% oxygen, or 52.6% TiO_2 . This analysis, however, is an ideal, and rarely seen in nature. In practice there will be some impurities present, including iron as Fe_2O_3 . Often iron is substituted by elements such as Mn and Mg with the result that naturally occurring ilmenite has a variable composition with a generic formula of $(\text{Fe}, \text{Mg}, \text{Mn})\text{TiO}_3$. Much of this variation in composition relates to the chemistry of iron, in particular the solid solution that exists between bivalent FeO and trivalent Fe_2O_3 , which is a function of geological history.

Ilmenite exists within the TiO_2 - Fe_2O_3 -FeO phase system. Although the terminology of end-member minerals of the TiO_2 - Fe_2O_3 -FeO phase system consisting of rutile, hematite, and wustite is generally well known, it can be difficult to find common definitions for intermediate minerals within the system, including ilmenite. Further, the definition of their alteration products is sometimes unclear.

The extent of solid solution of Fe_2O_3 in ilmenite is a function of the original geological origin. In many instances, Fe_2O_3 can be precipitated as hematite, which is typically the case in many east-African ilmenite deposits. In addition, even individual “ilmenite” grains can often contain a range of mineral types.

A clear distinction must also be drawn between what can loosely be termed “ilmenite-containing products” and the various individual minerals present, which may include the mineral ilmenite. Depending on the specific methods used to separate this product, the spectrum of minerals present may include nontitanium minerals having similar physical properties to ilmenite and a variety of titanium and iron-bearing minerals, including the weathered products of those minerals.

For the purpose of this chapter, ilmenite is defined as a product consisting of a combination of minerals, predominantly containing titanium and iron in various states of weathering, and having a TiO_2 content in the range of 35% to 65%.

It is therefore important to clearly understand the definitions of titanium-bearing minerals, which also involves an understanding of their relationship with iron minerals.

Definitions of Major Titanium-Bearing Minerals

The 1996 classification scheme of Buddington for describing the minerals of the TiO_2 - Fe_2O_3 -FeO system has been adopted. The mineral nomenclature follows, and Table 2 summarizes the geological source of the minerals.

- Rutile is an optically homogeneous, essentially pure, common form of TiO_2 . It forms tetragonal crystals.
- Anatase is a polymorph of rutile forming a blue or black tetragonal phase at low temperatures.
- Brookite is a rare metastable form of rutile and anatase, formed by the alteration of other titanium minerals, with a nonorthorhombic crystal structure.
- Ilmenite is a homogeneous, hexagonal phase consisting of $\text{FeO} \cdot \text{TiO}_2$, with less than 6% Fe_2O_3 in solid solution.
- Ferrian-ilmenite is a homogeneous, hexagonal phase consisting of $\text{FeO} \cdot \text{TiO}_2$, with 6% to 13% Fe_2O_3 in solid solution.
- Magnetite is a nonoptically homogeneous, spinel phase with a formula close to Fe_3O_4 , containing less than 5% TiO_2 .
- Titanomagnetite is a single-phase, homogeneous, cubic mineral, with Fe_3O_4 as the dominant phase, but containing more than 5% TiO_2 .
- Hematite is a hexagonal-trigonal phase with a formula approaching Fe_2O_3 , containing less than 5% TiO_2 .
- Titanohematite is hematite with greater than 5% TiO_2 , usually as $\text{FeO} \cdot \text{TiO}_2$ in solid solution, with a little excess TiO_2 .
- Pseudorutile is a hexagonal mineral, originally referred to as arizonite, formed by the alteration of ilmenite, with a composition approximating $\text{Fe}_2\text{Ti}_3\text{O}_9$ or $\text{Fe}_2\text{O}_3 \cdot 3\text{TiO}_2$.
- Altered ilmenite is a general term used to describe the alteration products of ilmenite, having a chemical composition between ilmenite and pseudorutile. Altered ilmenite need not be optically homogeneous and is essentially amorphous, although submicroscopic intergrowths of ilmenite and pseudorutile may be present.
- Leucoxene is a general term for the higher TiO_2 alteration products of all titanium-bearing minerals. Leucoxenes are distinguished optically from rutile by their characteristic internal reflections, although they may consist almost entirely of cryptocrystalline rutile or anatase in the final stages of alteration.

Table 2. Naturally occurring common titanium minerals and their geological occurrence

Mineral	Formula	TiO ₂ , %	Geological Occurrence
Ilmenite	FeTiO ₃	45–53	Common accessory mineral in most igneous and metamorphic rocks. Common detrital mineral.
Rutile	TiO ₂	95–100	Common accessory mineral in medium- to high-grade metamorphic and igneous rocks. Common detrital mineral and alteration product of ilmenite and other titanium minerals.
Anatase	TiO ₂	95–100	Low-temperature polymorph of rutile. Usually secondary, formed by the alteration of other titanium minerals.
Brookite	TiO ₂	95–100	Metastable polymorph of rutile and anatase. Found in cavities, fissures, and veins. Weathering product of other titanium minerals. Relatively rare.
Pseudorutile	Fe ₂ Ti ₃ O ₉	60–65	Alteration product of ilmenite in sediments. Common phase in altered ilmenite concentrates.
Altered Ilmenite	FeTiO ₃ –Fe ₂ TiO ₉	53–70	Term for the alteration products of ilmenite consisting of mixtures of ilmenite, pseudorutile, and leucoxene. Common in heavy mineral sands.
Leucoxene	High TiO ₂	70–100	Term for high TiO ₂ alteration products of ilmenite and occasionally sphene, usually consisting of microcrystalline rutile, or anatase, with minor pseudorutile, ilmenite, hematite, or goethite.
Titanite (sphene)	CaTiSiO ₅	40	Widely distributed accessory mineral in intrusive igneous, low-grade metamorphic rocks and as a detrital mineral.
Perovskite	CaTiO ₃	58	Accessory mineral in metamorphic and igneous rocks.
Pseudobrookite	Fe ₂ TiO ₅	33	Accessory mineral in igneous rocks. Forms as an oxidation product of ilmenite and titanomagnetite.
Ulvöspinel	FeTiO ₄	36	Accessory mineral in basic igneous rocks, usually found as exsolution lamellae in magnetite.
Titanomagnetite	(Fe,Ti) ₃ O ₄	0–34	Term for optically homogeneous Fe–Ti spinel containing magnetite and ulvöspinel in solid solution. Common accessory in basic igneous rocks.
Titanohematite	(Fe,Ti) ₂ O ₃	0–30	Term for optically homogeneous hematite–ilmenite. Common accessory in acid intrusive and anorthosite suites.

Composite Grains

In practice, composite grains can often be present in less weathered or more complex resources. Typical composite grains include

- Ilmenite plus altered ilmenite or pseudorutile, in any proportions
- Leucoxene plus ilmenite plus altered ilmenite or pseudorutile, in any proportions
- Ilmenite plus exsolved hematite or hematite plus exsolved ilmenite, plus the alteration products of ilmenite, i.e., altered ilmenite (plus pseudorutile) and leucoxene
- Magnetite plus exsolved ilmenite and their alteration products; i.e., the magnetite may be partly altered to hematite and ilmenite to the alteration products listed

Properties of Titanium-Bearing Minerals

Ilmenite

Ilmenite has a hexagonal crystal structure with thick tabular crystals and prominent basal planes, plus smaller rhombohedral truncations. The characteristics of this opaque crystal are close to those of hematite and similar to those of corundum, Al₂O₃. The ilmenite crystal structure has alternate octahedrally coordinated iron and titanium layers. A significant feature is the strength of the titanium-oxygen bond, represented as TiO₂. This bond is extremely difficult to break, so natural changes to ilmenite basically occur by the reordering or reaction of the iron layers, which affects magnetic susceptibility. Ilmenite typically has a hardness of 5.5 to 6.0 on the Mohs scale. Pure ilmenite has a melting point of 1,392°C.

Ilmenite from sedimentary sources occurs as homogeneous, subrounded to well-rounded, slightly elongated grains. These grains typically vary in size from 75 µm to 250 µm. In reflected light, and under oil, ilmenite is pinkish-brown and strongly anisotropic. The anisotropism colors are characteristically blue to green. The reflectance of ilmenite is close to that of magnetite and rutile, less than that of hematite, and greater than that of chromite.

Pseudorutile

Altered ilmenites are bluish-gray, compared to the pinkish-brown of ilmenite. The other optical properties of altered ilmenite are initially similar to those of ilmenite, but as alteration increases, anisotropism decreases. Eventually, ilmenite becomes isotropic pseudorutile.

Pseudorutile resembles rutile in color and reflectance (Table 2), although, unlike rutile, it is isotropic. The optical distinction of pseudorutile from altered ilmenite is complicated by the fact that altered ilmenite may also be isotropic. Pseudorutile is so fine grained that the properties of the hexagonal crystals cannot be discerned, making microscopic identification difficult. It can be clearly identified, however, by x-ray diffraction.

The upper TiO₂ content of pseudorutile is about 65%, and this value is often used as the cutoff between altered ilmenite and leucoxene compositions. Comparing the compositions of altered and unaltered ilmenites, it is clear that the titanium contents of the former are higher and that there is a corresponding decrease in iron with increasing TiO₂ levels.

Leucoxene

Leucoxene is easily recognized because it displays very bright, strong brown, yellow, fawn, and white internal reflections in both plane polarized and cross-polarized light. In reflected light, leucoxene is similar in color and reflectivity to rutile. The color and brightness of the internal reflections appear to be related to the TiO₂ content of the leucoxene, with brown indicating lower TiO₂ levels than yellow or white. As TiO₂ content increases, so too do the intensity and brightness of the internal reflections. Under cross-polarized light, leucoxene reveals a characteristic sugary texture.

Leucoxene grains are usually subrounded, often nonhomogeneous, and always pitted and porous to varying degrees.

Rutile

Rutile as found in most mineral sands deposits is characterized by its translucence and “foxy” red color. The prismatic crystal form

Table 3. Simple classification of titanium mineral deposits

Deposit Type	Typical Examples
Primary rock deposits	
Massif anorthosite	Lac Allard, Quebec Tellnes, Norway
Layered mafic type	Rooiwater, South Africa Stoffberg, South Africa
Sedimentary deposits	
Coastal environment	
Quaternary age	
Strand line	Capel, Western Australia Eneabba, Western Australia Trail Ridge, Florida Chavara, India
Aeolian	North Stradbroke Island, Queensland Richards Bay, South Africa Corridor Sands, Mozambique
Pre-Quaternary age	Murray Basin, Australia Camden, Tennessee Bothaville, South Africa
Alluvial environment	Gbangbama, Sierra Leone

that is evident in rutile in situ within igneous rocks is rarely preserved in rutile from mineral sands. Although more commonly translucent, rutile may be translucent to opaque. In the translucent phase, it exhibits parallel extinction and has a high refractive index with very high birefringence. The mineral may also be pleochroic. In reflected light, rutile is grayish white and anisotropic. The mineral is characterized by strong internal reflections and moderate reflectivity.

Other Minerals

Other minerals naturally occur with ilmenite, so, depending on methods of separation, they can be present in a commercial ilmenite product. Minerals that commonly occur with ilmenite are as follows:

- **Magnetite and titanomagnetite:** Magnetite and titanomagnetite are evident in ilmenite resources in Africa. When included in the magnetic fraction with ilmenite, the low TiO₂ contents of magnetite and titanomagnetite dilute the quality of the final ilmenite product.
- **Hematite and titanohematite:** Hematite generally occurs as discrete, homogeneous, occasionally porous, light-gray to white grains. Titanohematite is grayer than hematite, has a lower reflectance, is slightly less anisotropic, and does not display internal reflections. These minerals have to be removed because they dilute the quality of the ilmenite product.
- **Chromite:** Chromite is probably the most important particulate impurity occurring with ilmenite and has proved difficult to remove. Chromite has the composition FeCr₂O₄, or FeO•Cr₂O₃, and is a member of the complex spinel group of minerals to which magnetite also belongs.
- **Magnesia spinel:** The mineral spinel, MgAl₂O₄, can occur quite commonly and can lead to excessive MgO levels in some ilmenite products.
- **Other minerals:** Other minerals that may contaminate an ilmenite product include garnet, tourmaline, staurolite, and the aluminum silicates—sillimanite, andalusite, and kyanite.

Geology of Titanium Deposits

Titanium sources can be conveniently grouped into two simple classifications: (1) primary rock deposits and (2) sedimentary deposits (Table 3).

Sedimentary deposits are currently the world's major source of titanium, accounting for approximately 75% of the TiO₂ contained in total ilmenite production in 2003. The focus on titanium production from sedimentary deposits is primarily due to their easy accessibility and low mining costs. Because these deposits are mostly located on or close to existing coastlines, however, their exploitation can be environmentally sensitive and there are increasingly significant land-use conflicts. In the longer term, therefore, primary rock deposits may come to play a greater role in the sourcing of titanium.

Primary Rock Deposits

Ilmenite deposits occur in igneous rocks, particularly those related to massif-type anorthosites. Very large quantities of ilmenite also occur within layered mafic intrusions, which are also igneous in origin but are less commercially important because of extensive intergrowth of ilmenite with magnetite.

The two most important commercial deposits of the massif anorthosite type are the Lac Allard deposit in Quebec and the Tellnes deposit in southern Norway. In both these deposits, ilmenite occurs in close association with hematite and magnetite, resulting in ilmenite concentrates containing relatively low levels of TiO₂. Other deposits of the anorthosite type that have been mined in the past include those in the Sandford Lake District of New York State, the Roseland District of Virginia, and the Otanmäki deposit in Finland. Other anorthosite ilmenite deposits include the San Gabriel Range in California, the Duluth Complex in Minnesota, and the Laramie Range in Wyoming. Deposits of this nature are relatively common and, in the absence of the more economic sedimentary deposits, could potentially contribute a significant proportion of required ilmenite supplies in the future.

A characteristic of anorthosite-type deposits is that the host rocks are typically alkaline, which generally results in ilmenite concentrates having elevated levels of the alkaline oxides, CaO and MgO. Consequently, these deposits are generally not sources of chloride-grade ilmenite, although chemical processing to remove the alkali content (such as QIT's UGS process) can produce suitable quality chloride feedstock.

Perhaps the most noticeable occurrences of ilmenite in layered mafic-type deposits are those in the Bushveld Complex, South Africa. Examples include deposits that have been mined for their magnetite and vanadium content, the Rooiwater deposit, and the Stoffberg deposit. Sections of the Rooiwater deposit have been weathered to grains of free ilmenite, and it has been reported that ilmenite can be recovered by milling of the primary ore. In the other deposits, however, the close association of ilmenite and magnetite makes the recovery of free ilmenite difficult, so these deposits have not produced economic operations.

In China, high alkali content ilmenite is produced from a very large titaniferous magnetite deposit at Panzhihua in Sichuan Province. This deposit, which is also mined for iron ore, is China's principal source of ilmenite. A titaniferous magnetite deposit is also being investigated at Pipestone Lake, Manitoba, Canada.

Sedimentary Deposits

The weathering and erosion of titanium minerals from igneous and metamorphic rocks, followed by fluvial transportation and subsequent deposition and reworking, result in the formation of sedimentary deposits on coastal shorelines and in river beds and deltas. This weathering and transportation process results not only

in the formation of high-grade concentrations of titanium minerals as found on current and old shorelines but also in the chemical alteration of ilmenite grains caused by both oxidation and leaching by mildly acidic groundwaters.

When an area of titanium-bearing rocks is eroded, streams readily remove quartz and other light minerals and tend to sort the heavier minerals according to specific gravity, grain size, and shape. Deposition of fine, heavy minerals is most significant where streams enter the sea. Following deposition, these deposits are reworked by the combination of wind and wave action, with cyclonic storm events being the most significant mechanism of reworking to form high-grade strand line deposits on the shoreline. Today, such deposits can be observed on beaches as black layers, although often the quantity of mineral is relatively small and not sufficient to justify economic exploitation. When these strand lines accumulate over a long period of time during conditions of receding sea level, however, a series of strand lines can form that can constitute a major deposit of heavy minerals. Many such deposits have been found on ancient shorelines, which are now some tens of kilometers from the sea and may be covered with unmineralized sand.

Sedimentary Coastal Deposits

Most commercial sedimentary deposits of this type are found on shorelines of Quaternary age (0 to 2 million years). They include beach, or strand line, deposits and coastal aeolian dunes. The dunal deposits have been formed by wind transportation of sand from beach deposits, often resulting in the formation of very large deposits of lower-grade concentrations.

Typical Quaternary age sedimentary deposits, including both strand line and dunal concentrations, include the following:

- Deposits on the east coast of Australia, such as those on North Stradbroke Island
- The west coast of Australia, including deposits at Capel and Eneabba
- The east coast of southern Africa, including deposits around Richards Bay and those discovered more recently on the coastal plain of Mozambique
- Very recently formed deposits on the east and west coasts of India
- Deposits on the east and west coasts of Sri Lanka
- Deposits in Florida and Georgia in the United States

Pre-Quaternary deposits may be well above existing sea levels and often many hundreds of kilometers from the present coastline. In most instances, these deposits are highly altered, resulting in complex mineralogy, and typically include ilmenites with relatively high TiO₂ contents.

Examples of such deposits include the following:

- The Lakehurst deposit in New Jersey, which was mined in the past
- Deposits in the Murray Basin region of southeastern Australia, that are currently the subject of widespread exploration interest, with the announcement of two significant project developments in 2004—the Douglas and Pooncarie projects
- The McNairy sand deposits, Tennessee, which include the fine-grained Camden deposit that has been reinvestigated over recent years
- Upper Cretaceous deposits in the western United States

In some instances, natural weathering processes over long periods of time have resulted in the cementation of the mineral grains into consolidated sandstone, which may require crushing

and grinding to recover the heavy minerals. The Bothaville deposit in South Africa is one such example of a high-grade, significantly altered deposit of ilmenite that was once a series of coastal strand lines but today is observed as surface layers of iron-cemented sandstone.

Sedimentary Alluvial Deposits

Although most sedimentary mineral sands deposits have been formed in coastal environments, some have formed as alluvial deposits in river beds and deltas. Such deposits are often less well sorted than those in coastal environments, because they have not been subject to the high-energy environment associated with coastal storms. As a result, alluvial deposits may exhibit a greater range of particle sizes and may contain a broader range of minerals than is commonly found in coastal deposits.

Examples of such deposits include

- The rutile (and minor ilmenite) deposits at Gbangbama in Sierra Leone
- Alluvial tin deposits in Malaysia, from which ilmenite has been recovered as a by-product

Identified Resources

The major difficulty that arises in quantifying titanium mineral resources is the range of standards that individual countries and companies apply to the categorization of resources. The most significant aspect is the potential economic viability of reported ilmenite resources. In many classifications of mineral resources, such as that published by the Joint Ore Reserves Committee of the Australasian Institute of Mining and Metallurgy (the JORC Code), classification as a resource necessarily implies some potential for economic extraction. This standard, however, is not universally applied.

The U.S. Geological Survey (USGS) publishes titanium resources in its annual *Mineral Commodity Summaries*, using a consistently applied definition of resources and reserves. Table 4 shows the most recent USGS data on world ilmenite resources.

Analysis of global titanium resources by geographical region yields a significant difference in the geographical distribution of ilmenite resources associated with existing operations, compared with potential sources. Significantly, the undeveloped mining potential of Africa, including South Africa, Mozambique, Madagascar, and Sierra Leone, dominate global titanium resource potential. Of these, Mozambique accounts for more than half of Africa's total resources, all of which have been identified in the past two decades.

It is significant that in the estimation of TZ Minerals International (TZMI), approximately 50% of identified global titanium resources contain ilmenite of a quality that will necessitate beneficiation for use in TiO₂ pigment production. Most of these resources are of a quality that would probably be uneconomic for SR production under current technologies and cost structures unless iron wastes could be converted to saleable products. Consequently, the production of titanium slag will continue to play a significant role in the future supply of titaniferous feedstocks in the absence of improved SR technologies.

Brief Country Overview

Australia. Although Australia is the world's largest supplier of traded ilmenite, it accounts for only 14% of total identified ilmenite resources. The major portion of these resources is associated with existing operations in the Bunbury/Capel region, south of Perth, and in the Cooljarloo/Eneabba region, north of Perth in Western Australia. All deposits currently controlled by Iluka Resources in

Table 4. USGS summary of ilmenite and rutile resources (2003), in Mt of contained TiO₂*

Country	Reserves [†]	Reserve Base [‡]
Australia	141	183
Canada	11	13
India	21	26
Norway	18	18
South Africa	38	128
Ukraine	6	10
United States	4	37
Other countries	32	58
World total (rounded)	270	470

Source: USGS 2004.

* Reported by USGS in ton of ilmenite and rutile, converted by TZMI to contained TiO₂ using estimated TiO₂ contents as follows:

Australia:	ilmenite	60% TiO ₂ , rutile 96% TiO ₂
Canada:	ilmenite	35% TiO ₂
India:	ilmenite	50% TiO ₂ , rutile 95% TiO ₂
Norway:	ilmenite	45% TiO ₂
South Africa:	ilmenite	48% TiO ₂ , rutile 94% TiO ₂
Ukraine:	ilmenite	60% TiO ₂ , rutile 95% TiO ₂
United States:	ilmenite	60% TiO ₂ , rutile 95% TiO ₂
Other countries:	ilmenite	50% TiO ₂ , rutile 95% TiO ₂

† Reserves are "that part of the reserve base which could be economically extracted or produced at the time of determination" (USGS 2004, p. 194).

‡ The reserve base is the in-place demonstrated (measured plus indicated) resource from which reserves are estimated. It may encompass those parts of the resources that have a reasonable potential for becoming economically available within planning horizons beyond those that assume proven technology and current economics. The reserve base includes those resources that are currently economic (reserves), marginally economic (marginal reserves), and some of those that are currently subeconomic (subeconomic resources).

Western Australia are included as resources associated with existing operations.

Potential deposits include low-grade resources on the central coast of Queensland, of which the Bayfield deposit is the largest; the Goondicum weathered-rock ilmenite deposit, also in Queensland; and more recent discoveries of heavy mineral in the Murray Basin region of southeastern Australia. Although this region is currently attracting significant exploration activity, the identified resources of ilmenite to date are relatively small, amounting to about 15 Mt of ilmenite. Given the relatively early stage of exploration work, though, significant additional resources could be located. The very large fine-grained ilmenite deposits investigated by the former CRA Limited, known as the WIM deposits, have not been included in the identified ilmenite resources because of the significant uncertainties associated with their potential economic viability.

Brazil. Identified ilmenite resources in Brazil are relatively small, basically the one existing ilmenite-producing operation at Mataraca on the north coast and a deposit known as Bujuru on the south coast of Brazil. Brazil also hosts very large resources of anatase that are not included in the tabulation of identified ilmenite resources.

Canada. Canada's major ilmenite resource is the Lac Allard deposit currently being mined by QIT. Additional deposits of titaniferous magnetite in northern Manitoba may ultimately prove to be potential sources of ilmenite suitable for titanium slag production.

China. The major source of ilmenite in China is the Panzhihua titaniferous magnetite deposit in Sichuan Province, which has

been the major source of ilmenite for TiO₂ pigment production in China for many years. Coastal-type sedimentary deposits occur on Hainan Island and on the southern coast in Guangdong and Guangxi provinces, but these are relatively small. There are a number of other reported deposits of ilmenite in both inland alluvial locations and other primary rock deposits; data on these potential resources, however, are very limited.

India. There are significant resources of 60% TiO₂ ilmenite on the western coast of India in Kerala State, although the population density in the region hinders exploitation of these deposits. Large deposits of 50% to 53% TiO₂ ilmenite have been identified in the western portion of Tamil Nadu State in the south of the country.

The eastern coast of India, encompassing the coastlines of Andhra Pradesh and Orissa states, contains very large deposits of 47% to 50% TiO₂ ilmenite. Currently, one of these deposits in Orissa State is being mined, and a number of others are being considered for possible development. Most of the ilmenite from this region, however, requires beneficiation before being suitable as feedstock for production of TiO₂ pigment.

Kenya. The exploration for mineral sands deposits along the coast of Kenya has been relatively recent, resulting in a number of deposits being located, one of which, at Kwale, is currently the subject of a final feasibility study.

Madagascar. Large deposits of 60% TiO₂ ilmenite in the southeast of the country have been investigated by Rio Tinto for many years, with a decision expected to be made on the development of the project in 2005. There are additional ilmenite resources on both the eastern and southwestern coasts of Madagascar. Ticom Limited is investigating the deposits located near Morombe on the western coast of the island.

Mozambique. Exploration of Mozambique's long coastline for heavy mineral sands has occurred in the last 15 years, and three large deposits have been located. The most significant is the Corridor Sands deposit in the south of the country, which is by far the largest undeveloped source of ilmenite. Although only three areas have been explored in any detail, there are known occurrences of heavy minerals along much of the coastline, one of which is the Moma deposit, which is being developed by Kenmare Resources.

Norway. Norway's ilmenite resources are contained in primary rock deposits, the most significant being the Tellnes ore body in the south, which is currently being mined to produce sulfate-grade ilmenite.

South Africa. South Africa's resources are widespread. The most important occur on the east coast, both north and south of Richards Bay in KwaZulu-Natal. Deposits have also been identified on the southeastern coast. There are reported heavy mineral occurrences along large sections of the western coast, and Namakwa Sands is now mining one such deposit. It is likely that additional occurrences along the western coast could increase the identified resources.

South Africa also contains large deposits of titaniferous magnetite in the Bushveld Complex, some of which are included in the estimate of ilmenite resources. A moderately large deposit of cemented, highly altered ilmenite at Bothaville has also been the subject of preliminary technical investigations.

Sri Lanka. Sri Lanka's ilmenite resources include high-grade beach deposits on the northeastern coast that are currently being mined, although the operation is severely affected by the civil war in Sri Lanka, and newly discovered large deposits of 48% to 50% TiO₂ ilmenite on the northwestern coast, which are being explored by Iluka Resources Limited and Consolidated Rutile Limited.

Ukraine. Large deposits of ilmenite in Ukraine have been mined for many years, primarily to provide titanium feedstocks for

pigment production in Ukraine and titanium metal production in both Ukraine and Russia. Since the mid-1990s, some ilmenite has been exported from Ukraine for SR production in the United States and, more recently, for sulfate pigment production in Eastern Europe and chloride pigment production in the United States. The resources are in two general areas known as Irshansk, containing ilmenite predominantly of 55% to 59% TiO_2 content suitable for sulfate pigment production, and Vilnohirsk with ilmenite containing 64% TiO_2 , but with high Cr_2O_3 content.

United States. Identified ilmenite resources in the United States are predominantly coastal-type sedimentary deposits in Florida, Georgia, and Virginia. Although rock ilmenite deposits have been mined in the past, none of these are currently included in identified ilmenite resources.

TECHNOLOGY

Mining and Concentration of Heavy Mineral Sands

Apart from two rock ilmenite operations, all titanium production is sourced from heavy mineral sands mining operations using dredging or dry mining techniques. The choice of method depends primarily on the physical nature of the deposit and the scale of operation. Dredging is the preferred and more economical choice for large-scale operations. Dry mining methods are used for smaller scale operations in situations where there is inadequate water, where the deposit contains hard, rocky material, or where there is a high clay content.

Dredging

Large-scale dredging operations typically use high-volume suction cutter or bucketwheel dredges operating at between 500 tph (7 Mtpy) and more than 3,500 tph (26 Mtpy), allowing for 85% availability. The excavated slurried sand is pumped directly to a wet concentration plant. Both the dredge and concentrator float in a pond of water and move forward as the mining operation progresses. The capital cost of a high-volume dredge and wet concentration plant is generally higher than the capital cost of the plant and equipment associated with a dry mining operation; the unit operating cost, however, is much lower. A principal cost component in pumping high volumes of high-density slurry is electricity, particularly if tailings have to be stacked at high levels. Hence, power costs are a major factor in the economics of the dredging operations.

Dry Mining

Dry mining operations typically involve using conventional earth-moving equipment (i.e., scrapers, excavators, and trucks or front-end loaders) to excavate the ore and transport it to a stationary wet concentration plant. Some mineral sands companies prefer to conduct their mining operations on a contract basis, thus avoiding the capital costs associated with purchasing mining equipment. Irrespective, the capital cost of these dry mining operations is typically lower than that for dredging, but the operating cost is considerably higher, unless heavy mineral grades are extremely high.

The economics of mining operations are further affected by the cost of transport of the ore from the mine to the concentration plant. If the concentration plant is fixed in one place, the distance between the mine and the plant can become substantial and the transport cost component significant. That is why it is typical for the concentration plant to be moved regularly (i.e., every 6 to 24 months) to reduce transport costs.

Mining of Rock Resources

There are only two operating rock ilmenite mines at the present time, in Canada and Norway, although possible further mines are

being investigated in Australia and Finland. There was a third operation at Otanmäki in Finland, which provided feedstock for Kemira's ilmenite-based TiO_2 pigment plant until the operation closed in 1984.

Lac Allard, Quebec, Canada

QIT's ilmenite deposit located 43 km inland from Havre St-Pierre on the St. Lawrence Seaway, 960 km from Montreal, was discovered in 1946. The ore body consists primarily of coarse-grained ilmenite with disseminated fine lenses of hematite. Associated with the ilmenite is the basic feldspar anorthosite. The ore being mined typically contains 32% to 36% TiO_2 . Mining in this operation is carried out using conventional open-pit methods in a horseshoe-shaped mine. Production exceeds 3 Mtpy.

Primary blasting is performed weekly during the months when the mine can be accessed, and the ore is trucked to a crushing station, where it is initially processed by a jaw crusher and then by a secondary cone crusher. The 75-cm ilmenite product is loaded in hopper cars for transport to Havre St-Pierre for shipment from April to December.

In all respects, this would be considered a relatively simple mining operation.

Tellnes, Norway

The other rock mining operation, owned by Titania (a subsidiary of NL Industries), is at Tellnes about 150 km northeast of Stavanger, Norway. The deposit was discovered in 1954 and, since 1960, has operated as a replacement operation for the Sandbekk deposit 2 km to the south, which was originally opened in 1916 to provide feedstock for the world's first sulfate process TiO_2 pigment plant.

In contrast to the Lac Allard operation, the Tellnes mining operation is somewhat more complex because of the nature of the anorthosite ore resource. The titanium ore exists as intrusives in the anorthosite massif, but in this instance it is associated with far greater quantities of magnetite and sulfide minerals. Annual production from the open-pit mine is about 2 Mt of ore and 1.6 Mt of waste rock. After blasting, the ore is transported to a primary crusher, where its size is reduced to 200 to 250 mm.

To remove some of the unwanted constituents, it is first necessary to grind the ore. Gravity and magnetic separation stages are then used to remove magnetite, and finally flotation removes the sulfide minerals.

Processing of Mineral Sands

Wet Concentration

Mineral sand deposits contain from less than 1% to more than 10% heavy mineral in some Australian operations, to more than 20% in some Indian operations. Wet concentration plants separate the heavy minerals from the silica sand to make a heavy mineral concentrate (HMC) containing 90% to 97% total heavy mineral. This process involves, first, separating the sand from rocks and pebbles by screening, followed by separating the fine clay particles (slimes) from the sand, typically using hydrocyclones. Where the clay content of the ore is low, this slime separation stage is not necessary. Many current deposits, however, have a relatively high clay content, and slime separation is becoming an increasingly important aspect of mineral sands operations. The slimes, and most of the water, are then either pumped directly into slime-settling ponds or passed to a mechanical thickener where the solids content of the slimes is increased and a large portion of the water is recovered. The thickened slimes and sand tailings are then pumped back into the mined-out area.

Table 5. Physical characteristics of minerals used for mineral separation

Mineral	Specific Gravity	Magnetic Susceptibility	Conductivity
Ilmenite	4.6–4.8	High	High
Pseudorutile	4.2	High	High
Rutile	4.2	None	High
Leucoxene	3.5–4.2	Weak	High
Sphene	3.5	Weak	Weak
Magnetite	5.2	Very high	Very high
Hematite	5.3	Moderate	Moderate
Chromite	4.5–4.8	High	Moderate
Zircon	4.7	None	None
Monazite	4.6–5.4	Moderate	None
Garnet	3.5–4.3	Moderate	Weak
Kyanite	3.6	None	None
Staurolite	3.7	Weak	None
Quartz	2.7	None	Weak

After the removal of oversize and slimes, the heavy mineral particles are separated from the lighter silica sand using either spiral separators or cone concentrators. The sand slurry is repeatedly passed over sequential stages of the separating equipment, so that more than 90% of the heavy minerals are recovered from the sand. The resultant HMC is then transported to the dry separation plant. For some operations, a separate ilmenite-rich concentrate is also extracted using wet high-intensity magnetic separators (WHIMSs).

Ilmenite Separation

Separating ilmenite as a final mineral product from heavy mineral sands deposits is achieved by using the different magnetic and conductive properties of the various minerals present. Further separations are based on either grain size or specific gravity. Table 5 lists the key physical characteristics of those minerals that can be present with ilmenite.

Ilmenite is typically extracted first because of its preponderance in the mineral suite. Where there are minerals present that make recovery difficult, these are extracted first. In all cases, pseudorutile and ilmenite constitute the majority of the final ilmenite product.

Ilmenite Recovery

Potential losses of heavy mineral occur at each stage of ilmenite production: mining, wet concentration, and dry processing.

Some of the heavy mineral present in the resource may not be recovered because of difficult mining conditions or mine planning decisions about the minimum economic grade to be mined. Mineral recovery usually refers to the percentage of heavy minerals recovered from the ore mined. Losses in the mining operation are generally not included in this calculation, although they are taken into account when expressing recovery from the original mineral reserves.

Heavy mineral is lost in the gravity separation processes in the wet concentrator and at numerous points in the dry separation process. Typical average heavy mineral recoveries in the wet concentration process are approximately 85% to 95%, with the minerals of highest specific gravity exhibiting highest recovery. Normal recovery rates for ilmenite are 90% to 95%.

Dry mill recovery of ilmenite is also typically in the range 92% to 95%, making the overall mining and processing recovery in the range 82% to 90%.

Beneficiation

Overview of Upgrading Processes

Because of the limited resources of naturally occurring, high TiO₂ minerals suitable for processing to TiO₂ pigment, the titanium feedstock industry has made a concerted effort since the early 1960s to develop upgraded products from ilmenite that can be used as substitutes for, or with, ilmenite or rutile. All upgrading essentially involves removing iron and, in some instances, minor impurities. Two types of intermediate products have been developed: SR and high-titania slag, generally termed *slag*.

The oldest form of upgraded product is Sorel slag (originally 72% TiO₂ and now 75% to 80% TiO₂) produced since 1951 by QIT in Quebec from the Lac Allard rock ilmenite deposits. The same technology has been applied to the upgrading of 47% TiO₂ ilmenite mined by Richards Bay Minerals in South Africa to produce an 85% TiO₂ slag. Similar technology is used at the Tinfos smelter in Norway, but with different processing before smelting.

Recently developed, direct current (dc) or plasma arc smelting technology is used by Namakwa Sands for its slag operation on the west coast of South Africa and by Ticon South Africa at Empanjeni, near Richards Bay.

In 1995, after many years of research, QIT announced the development of a chemical leaching process for upgrading its standard sulfate grade Sorel slag by removing MgO and CaO and some iron, resulting in an increase in TiO₂ content to approximately 95%. The product from this process is referred to as UGS, with an intermediate 83% TiO₂ product, heat-treated slag (HTS), also being produced that has achieved technical acceptance as an alternative to rutile.

A number of processes have been developed to upgrade ilmenite to 90% to 95% TiO₂ products, generically known as SR. These processes vary in the extent to which the ilmenite grains are reduced, in the precise nature of the reduction reaction, and in the conditions used in the subsequent leaching process to remove iron. All the existing commercial processes are based on the reduction of ilmenite in a rotary kiln, followed by leaching to remove the iron from the reduced ilmenite grains.

The Becher process for SR production has been used exclusively in Western Australia, where five kilns have about 700,000 t of SR capacity. The other SR plants, located in India and Malaysia, use partial reduction and HCl leaching techniques based on the Benilite process.

As the direct use of ilmenite for the production of TiO₂ pigment has declined, slag has become the most important titanium feedstock for the TiO₂ pigment industry. The production of slag is favored in situations where large quantities of moderately low TiO₂ ilmenite, relatively free of impurities, are available along with plentiful supplies of inexpensive electric power. This situation exists in Quebec, Norway, and South Africa. One of the economic advantages in slag production, compared to SR production, is that iron is recovered as a coproduct and provides a significant contribution to the revenue of slag producers. In SR production, iron is discarded as a waste product and therefore is a cost rather than a revenue source. Iluka Resources, however, the world's largest SR producer, is continuing research to make a marketable product by smelting the iron waste.

One of the disadvantages in the slag production process is that it provides no opportunity for removing most minor impurities that may be present in the original ilmenite and which become concentrated in the slag product. Consequently, the long-term production of slag is dependent on supplies of ilmenite with low impurity levels, unless further chemical processing (such as QIT's new UGS

process) is used to remove such unwanted impurities. Another disadvantage of slag is the retention in the product of about 10% FeO, which generally limits the TiO₂ content to an upper level of around 86% and, more important, requires the use of extra reagents and waste treatment facilities at TiO₂ pigment plants.

The Becher process for SR production suffers a similar disadvantage in relation to impurity removal, although it can remove approximately half the manganese content in the ilmenite if sulfur is added in the process. Acid leach SR processes are more flexible in their ability to remove unwanted minor impurities present in the ilmenite, and, in the longer term, as naturally available high-purity ilmenite supplies decline, such processes may gain added favor in the feedstock production industry, subject to satisfactory economics.

Slag Production

Smelting of ilmenite to produce titanium slag is conducted at five major Western world operations:

1. QIT at Sorel, Quebec, Canada: capacity 1.2 Mtpy
2. Richards Bay Minerals, Richards Bay, South Africa: capacity 1.0 Mtpy
3. Tisor South Africa, Empangeni, South Africa: capacity 250,000 tpy
4. Tinfos Titanium and Iron KS, Tysseidal, Norway (Tinfos): capacity 200,000 tpy
5. Namakwa Sands Limited, Saldanha Bay, South Africa: capacity to 205,000 tpy

In addition, titanium slag is produced at Panzhihua in China, Berezniiki in Russia, and Ust-Kamenogorsk in Kazakhstan.

The most important factor for the location of an ilmenite smelter is the availability of cheap electric power, because the electric arc furnaces used to smelt the ilmenite are high power consumers. The ilmenite treated by the smelters above typically contains 36% to 50% TiO₂. These lower TiO₂ ilmenites are the preferred feedstock for smelting, because the high iron content provides suitable thermodynamic conditions for smelting and high-grade pig iron is produced as a valuable coproduct.

The quality of the slag produced is directly related to the level of impurities in the ilmenite, many of which pass directly to the slag rather than the pig iron. Among these are the alkali oxides, calcium and magnesium, which are the most important impurities generally associated with the lower TiO₂ ilmenites. The radionuclides thorium and uranium, which would report to the slag if present in the ilmenite, are generally in very low concentrations in the lower TiO₂ ilmenites used as feedstock and therefore present no problems.

Two grades of slag are produced that are readily identified by their alkali (MgO and CaO) content and the difference in TiO₂ levels, which is a consequence of the impurity content. Both South African slag products have relatively low MgO levels, with the maximum being 1.1%, and relatively high TiO₂ levels at 85% to 86%. These slags are suitable for production of TiO₂ pigment by the chloride process because the upper limit of combined MgO and CaO content for that process is 1.6%, with a preferred limit of 1.0%. Chlorinatable slag is a preferred product because of its greater market potential and higher value.

Sorel slag and the slag produced by Tinfos from Tellnes ilmenite have high MgO contents, 5.0% and 7.9%, resulting from ilmenite MgO impurity levels of 2.9% and 4.6%, respectively. The TiO₂ contents are lower, in the range of 75% to 80%, and these slags are suitable only for the sulfate process.

Sulfate-grade slag has a wide particle size range to tolerance because it has to be ground before being digested with sulfuric acid.

In contrast, chloride-grade slag has a tighter particle size specification range because of the "blow-over" of fine particles in the chlorination process. As a consequence, chloride-grade slags with particles less than 100 µm are used in some sulfate process plants, even though the presence of more rutile phase in the slag product means that recovery of TiO₂ units is slightly lower.

Controlling the particle size of chloride slag is therefore critical. Technology is progressively evolving so that now only 10% to 20% of this slag product has to be used in the sulfate process.

In July 1997, Tinfos began smelting ilmenite from BHP's Beenup project in Western Australia, which was low in CaO and MgO and therefore allowed production of mainly chlorinatable slag. With the closure of the Beenup project in 1999, Tinfos returned to making sulfate slag from Tellnes ilmenite.

The Cr₂O₃ level in ilmenite feedstock has to be controlled because it affects the quality of coproduct iron. Ilmenite roasting is used at Richards Bay Minerals for this purpose and is planned to be installed in the smelter stage of the operation proposed by Iscor Heavy Minerals Limited, for development of its deposits near Richards Bay.

Key Operations in Slag Making

A temperature in the range of 1,650°C to 1,700°C is required to ensure that the thermodynamics of the process work correctly.

It is also important that excessive amounts of a rutile phase are not formed, particularly for slag used in the sulfate process. For the sulfate process, it is also important that M₃O₅ phase forms correctly, because this phase is soluble in sulfuric acid. (M₃O₅ is a general term describing a range of metal oxides.)

It has to be recognized that one of the limiting factors in ilmenite smelting is the inability to reduce the FeO beyond a given level. In essence, two main reactions are occurring in parallel:

1. $\text{FeO} + \text{C} = \text{Fe} + \text{CO}$
2. $\text{TiO}_2 + \text{C} = \text{Ti}_2\text{O}_3 + \text{CO}$

As the FeO levels decline, the TiO₂ level increases, which requires higher operating temperatures because of the fluxing role that FeO provides. This clearly places a limit on the effective level of FeO that can be produced in a typical slag, which is generally considered to be in the range of 8% to 10%.

This requirement for high temperature also places a restriction on the refractories in the furnace, which have to be water-cooled to ensure that a layer of slag is built up on the inside of the steel lining to prevent melting of the furnace wall, which has occurred by accident on several occasions.

The impurity oxides of chromium, silicon, vanadium, and manganese are also partly reduced to the metal and oxygen. The following partition ratios between slag and iron, expressed as percentages reporting to the slag, apply:

- V₂O₅, 20%
- MnO, 80%
- Cr₂O₃, 20%
- SiO₂, 40%

All other impurities report entirely to the slag.

Upgraded Slag

For many years, QIT actively sought ways to improve the quality of its Sorel slag product by reducing iron and MgO levels to produce a new high-grade feedstock product suitable for the chloride process.

In February 1995, QIT announced plans to build a new plant at Sorel to manufacture a 95% TiO₂ product to be known as UGS. The plant began operating in late 1997, and the product has

achieved technical acceptance to the extent that the plant is now being expanded to 325,000-tpy capacity.

The UGS process has three stages:

1. Sizing of the slag, which helps to partly reduce the M_3O_5 phase in the feed
2. Heat treatment to facilitate the leaching of FeO, MgO, and CaO
3. Hydrochloric acid leach

The final process steps are similar to those for acid leach SR.

Synthetic Rutile

SR is manufactured commercially using two main technologies: the Becher process and the Benilite process. The end product of both processes is a high TiO_2 (90% to 93%) feedstock designed for the chloride process, with slightly lower equivalent titanium content and a slightly finer particle-size distribution than rutile. Both technologies remove iron through ilmenite reduction and the subsequent leaching of iron, but there are minor differences.

Becher SR Process

Development. The Becher process was developed in Western Australia in the late 1960s to process ilmenite with TiO_2 levels that lay outside the relatively narrow specifications dictated by sulfate pigment plants. Western Australian feedstock producers had quantities of ilmenite typically about 55% TiO_2 that could not be sold directly to the pigment industry and therefore sought new markets for the material. Upgrading the TiO_2 content of ilmenite to about 90% produced a suitable feedstock for chloride process pigment manufacture.

With access to a low-impurity ilmenite source and a suitable reducing agent—subbituminous coal—a process was developed whereby the iron oxide content of the ilmenite is converted to metallic iron in a rotary reduction kiln at 1,050°C to 1,150°C and then removed by accelerated corrosion rather than acid leaching. To treat 55% TiO_2 ilmenite, a preoxidation step was required to convert FeO to Fe_2O_3 , to reduce kiln retention time. The preoxidation stage was eliminated in the late 1970s when 60% TiO_2 Eneabba ilmenite started to be used, resulting in a significant cost saving. The process is currently used only to treat ilmenites with 58% to 63% TiO_2 content derived from a number of producers in Western Australia.

An improvement made in 1975 removed approximately 50% of the manganese from the ilmenite, whilst simultaneously further reducing the iron content from 3.5% to 2.5% and improving the TiO_2 content from 90% to 93%. This improvement was achieved by adding sulfur or sulfates to the kiln and then adding a final acid-leaching step. The process with sulfur doping and acid leaching is known in some quarters as the improved Becher process, whereas the initial process, without the improvements, produces a standard-grade 90% TiO_2 SR.

Process Details. The improved Becher process, which operates most effectively with a 60% to 63% TiO_2 ilmenite feedstock containing a majority of pseudorutile, has three main processing steps:

1. The first step in the process is to reduce the iron content of the ilmenite to its metallic state. Iron, coal, and sulfur are fed into a rotary kiln with an exit temperature of 1,050°C to 1,150°C. The iron content of the ilmenite is reduced to metallic iron, and there is a partial reduction of the TiO_2 to Ti_2O_3 . The sulfur reacts with the iron and manganese content to form a complex sulfide phase that is subsequently removed with sulfuric acid. Oversize particles are removed together with waste char, before the reduced ilmenite passes on to the aeration stage.
2. Reduced ilmenite is mixed with aerated water and ammonium chloride catalyst in batches. The metallic iron within the

ilmenite particles is dissolved in the solution and diffuses in the form of complex ions to the grain surface. Here it is oxidized in the presence of oxygen-rich water to iron oxides and hydroxides, which are insoluble and so precipitate out of solution and are removed as waste.

3. The resultant iron-depleted ilmenite is leached in a weak sulfuric acid solution to remove the manganese sulfides and any residual metallic iron. The SR is then washed, dewatered, and dried ready for dispatch.

The SR product of the Becher process typically contains 90% to 93% TiO_2 , depending on the initial ilmenite quality. The product can be quite friable because of the dissolution of iron from the ilmenite lattice.

The typical reduction products contained in reduced ilmenite from the Becher kiln are rutile, reduced rutile, iron, and ferrous pseudobrookite. The ferrous pseudobrookite, also known as M_3O_5 phase, is a minor phase that contains a small proportion of the original iron in the ilmenite. It is stabilized at kiln temperatures above 1,050°C by impurity elements contained in the ilmenite such as manganese, magnesium, aluminum, uranium, and thorium. These impurities are held in this M_3O_5 phase, which is insoluble in dilute acid. Apart from manganese, which can be partially removed by sulfidization, all impurity elements are therefore retained in the SR.

At lower reduction temperature the impurity elements enter a metatitanate or rhombohedral phase M_2O_3 . This phase is soluble in hydrochloric acid and explains the greater success of the Benilite process in removing impurities.

The Becher process requires the higher reduction temperature to cause formation of metallic iron, which can be leached by the corrosion process at far lower cost. The synthetic rutile enhancement process (SREP) variation is an innovation, described later, that seeks to retain the advantage of metallic iron formation while allowing removal of some impurity elements, albeit at some cost.

The time required in the rotary kiln to achieve complete reduction of iron controls the rate of output, and thereby the efficiency, of the whole process. The retention time is a function of the weathered state of the ilmenite, although the FeO content is often used as a rough guide. In the weathering process, iron is leached out of ilmenite, leaving cracks and cavities in the grains that make them more permeable. In the reduction process, the carbon monoxide is then able to react with iron more quickly because of the changed physical properties of the grain.

Though unweathered/higher FeO ilmenites require longer kiln retention, it is also important to assess the homogeneity of the ilmenite feed. As all ilmenite feedstocks will contain particles with a range of chemical compositions and iron contents, 60% TiO_2 ilmenite may contain particles with as little as 2.0% FeO, and some with as much as 7.0% FeO. This distribution of FeO values in the individual particles that constitute the ilmenite feedstock determines the kiln retention time, with the process only as efficient as the least weathered component (i.e., the highest FeO levels).

RGC Mineral Sands Limited developed an SREP in the mid-1990s to reduce the U+Th levels of the SR produced from its Eneabba ilmenites to salable levels. The process is technically successful but expensive to operate.

The process depends on the phenomenon that at high enough temperatures (above 1,200°C) an impurity-rich phase appears on the surface of the mineral grains. Adding a flux lowers the reaction temperature, and the impurity-rich phase can be rendered soluble in a series of leaching steps.

At the Narngulu plant, the SREP process operated by Iluka is fully integrated with the existing Becher process. A borate-based

flux is added to the kiln and forms a glassy phase that provides a soluble sink for the manganese, magnesium, thorium, and uranium.

The Becher process is generally the most cost-effective method of SR production because iron is removed by corrosion rather than acid leaching. It is most effective with ilmenites containing about 62% TiO_2 and low FeO levels. There are limitations to the process, however: impurities other than iron and manganese cannot be removed unless a process such as SREP is used, which requires additional costly acid-leaching steps, and it is unsuitable for use with highly weathered ilmenites containing leucoxene. There are also costs associated with disposal of iron oxide and neutralized acid effluent.

Future Developments. With declining availability of 60% TiO_2 ilmenites, increased attention is now being focused on applying the Becher process to lower TiO_2 ilmenites. Possible modifications are

- Reinstating the preoxidation stage, which has the effect of artificially weathering ilmenite
- Accelerating the kiln reduction process by preheating the coal to 700°C to 800°C
- Using a combination of preoxidation of ilmenite and pre-drying coal

Using lower TiO_2 ilmenites would require higher input volumes of both ilmenite (because of the lower quality) and coal (to maximize kiln reduction). It is estimated that the combined effect would be to reduce kiln capacity by about 5% to 10% if a 55% TiO_2 ilmenite were used in place of a 60% ilmenite and preoxidation was reinstated.

Work carried out by Lurgi Metallurgie (now Outokumpu) on iron ores has potential application to ilmenite upgrading. The principal difference in the iron reduction processes is that a circulating fluidized bed (CFB) replaces the rotary kiln used for reduction in the Becher process. The advantages of the CFB largely apply to the coal requirement. Because it operates at lower temperatures, coal consumption is reduced and there is a greater flexibility in the coal type that can be used. The process is also believed to widen the range of acceptable ilmenite feedstocks. Overall, capital and operating costs are also said to be lower, but no commercial plant has yet been installed.

Some work has also been carried out on a possible hydrochloric acid leach stage of the reduced ilmenite in order to remove some of the impurities, such as Cr_2O_3 , MnO, MgO, and CaO, which are not normally reactive in the Becher kiln.

MARKETS

Uses for Titanium

TiO_2 Pigment

More than 93% of the world's titanium is used as TiO_2 pigment. Titanium metal consumption accounts for only 2.5% of total titanium usage; other end uses include metallurgical flux, welding-rod coatings, titanium carbide, titanates, and other titanium chemicals. Trends in the TiO_2 pigment industry, then, drive the exploitation of titanium mineral deposits.

In this respect, titanium is different from most of the other metallic elements. Ores containing aluminum, iron, copper, zinc, or nickel are mined primarily to satisfy demand for the metal, either unalloyed or in combination with additives to create alloys with enhanced properties. Thus, trends in demand for aluminum metal drive the search for and exploitation of bauxite deposits. By contrast, ore containing titanium is mined primarily to satisfy demand for a chemical product— TiO_2 pigment.

Nonrecyclability of TiO_2

The issue of recycling is one of fundamental importance in the iron and steel industry and in most nonferrous metal industries. In recent years, governments around the world have been keen to encourage the recycling of metals, partly on the grounds of minimizing the amount of consumer waste that has to be disposed of and partly on the grounds of conserving valuable nonrenewable resources. For a number of countries, increased recycling of metal can also help reduce the total import bill and therefore benefits the balance of payments.

For the mining and smelting sectors, trends toward increased recycling have an important effect insofar as recycled metal competes against metal derived from virgin ore. As recycling becomes more widespread, the demand for virgin ore is damped down. Moreover, if refiners are mandated to use recycled metal feedstock, or if they find it cheaper to do so, it places a ceiling on prices for the virgin metal ore. This can already be seen with lead, where recycled metal now accounts for about 50% of the world's total consumption.

Recycling also has a net effect on certain chemicals such as chlorine and sulfuric acid, both of which are used and can be recycled during the manufacture of TiO_2 . In terms of the world's total consumption of chlorine and sulfuric acid, however, recycled material plays a fairly minor role. For most chemical products, recycling plays no role at all.

Such is the case with titanium dioxide, which is mainly used as a pigment in paint, paper, plastics, inks, and rubber. The TiO_2 becomes so intimately incorporated into the end product that in most cases it is beyond the bounds of current technology to recover the TiO_2 values from consumer waste. Indeed, TiO_2 cannot even be economically recovered from scrap paint, paper, or pigmented plastics that have not yet left the factory.

The issue of recycling will continue to have little impact on trends in consumption and pricing in the titanium minerals and TiO_2 pigment industries.

Forms of TiO_2

Titanium dioxide occurs naturally in three crystalline forms: primarily anatase and rutile, with brookite a rare occurrence. Commercially manufactured TiO_2 is available as either anatase-type or rutile-type, categorized according to the crystalline form. Anatase pigment is currently made by sulfate process producers only; rutile pigment is made by both chloride and sulfate process producers.

Rutile-type is the thermodynamically more stable form. Anatase-type TiO_2 undergoes irreversible transformation to rutile-type TiO_2 above 700°C. The rate of transformation is affected by the presence of various other substances, which either catalyze or inhibit the reaction. Rutile has a more compact crystal structure, and this explains why it has a higher specific gravity and is harder and more abrasive than anatase. For some applications, particularly in the textile, rubber, and ceramics industries where abrasiveness is an issue, anatase is the preferred form of TiO_2 . In all other applications, either the anatase or rutile form can be used. Rutile grades are often favored because of their better hiding power and photochemical inertness. In the European inks and paper sectors, anatase tends to be more popular.

Other Uses

The other main consuming industries for titanium raw materials are

- Titanium metal (chloride slag, rutile, and SR)
- Fluxes for coating welding electrodes (rutile and ilmenite)

- Metallurgical fluxes in the iron and steel industry (ilmenite)
- Sandblasting and drilling muds (ilmenite)

These industries consume less than 10% of the total TiO_2 contained in the various grades of titanium raw materials. They can have a moderately important influence, however, on the demand for specific grades of raw material.

Titanium Metal

Titanium is a low-density, high-strength metal that is extremely resistant to corrosion. The metal's high strength-to-weight ratio makes it ideal for aerospace applications, which are its major markets. Use of titanium metal is gradually being extended into other transport areas as weight reduction and fuel economy become more important.

Because of titanium's corrosion-resistant properties, the metal is being used in specialized, corrosive environments in chemical process plants such as desalination plants.

The first stage in the production of titanium metal is the production of titanium sponge, a tradeable commodity. Only nine companies worldwide produce titanium sponge. Japan, Russia, and Kazakhstan are the largest producers, with smaller production from Ukraine, the United States, and China.

Commercial production of titanium metal dates back to the early 1950s. The most widely used manufacturing process is the Kroll process, which involves the reduction of titanium tetrachloride with molten magnesium to form titanium sponge.

Titanium sponge produced by metallic reduction processes contains significant quantities of impurities that are subsequently removed by leaching, vacuum arc remelting, and cold-hearth techniques. Several stages of remelting may be required to produce progressively purer titanium metal. The ultimate product from this purification process is known as titanium ingot.

Titanium ingot is fabricated into mill products (i.e., bar, sheet, plate, tubes, etc.) that are used for metal casting, the production of fabricated products, or as feed stock in the production of titanium alloys. The fabricating and machining stage of titanium metal generates significant quantities of scrap metal. Approximately 80% of new metal output is scrap that is recycled and contributes significantly to the total economics of the titanium metal business.

Titanium tetrachloride (TiCl_4), known as "tickle" in the industry, is produced through the chlorination of titanium raw materials and is an intermediate product in the chloride route process for pigment production. Titanium sponge producers either purchase titanium tetrachloride from pigment producers, a practice in the United States, or purchase titanium raw materials for chlorination.

The quality of titanium raw materials required for titanium sponge production is similar to that required for chloride route process pigment production. One distinction is that raw materials for titanium metal production generally require low levels of tin. Titanium sponge producers use chloride slag, rutile, and SR as raw materials.

Welding Electrode Flux

Titanium minerals are used as a component of fluxes for coating welding electrodes. The wide variety of flux compositions depend on the nature of the welding process, the materials to be welded, and the desired characteristics of the weld.

Titanium dioxide is most commonly added to welding electrode flux in the form of rutile. Leucoxene is also widely used, although some electrode producers prefer not to use it because of possible variations in its composition. Ilmenite has also been used as a low-cost substitute for rutile.

The most important requirement in flux raw materials is consistency of both particle size distribution and chemical composition. Phosphorus and sulfur are particularly deleterious impurities. Heavy minerals can also affect the quality of the weld. In general, silica, alumina, and alkaline earth oxides are not critical because they are a necessary component of the flux. It is important, however, that the content of these oxides be consistent.

Consumption of titanium minerals for welding electrode fluxes is estimated to have been about 100,000 tpy of TiO_2 units in the late 1980s, declining in the early 1990s because of the worldwide economic recession. The consumption of electrodes is influenced particularly by the construction industry and overall manufacturing activity. Demand for raw materials has since increased to an estimated 110,000 TiO_2 units. It is reported, however, that new continuous welding processes require lower TiO_2 content in the flux, which may limit the future growth in demand in this industry.

Metallurgical Flux

Lower quality titanium raw materials are used as a metallurgical flux in smelting operations, particularly in iron and steel production. Low TiO_2 ilmenite from Lac Allard in Canada and ilmenites from Southeast Asia and the east coast of Australia are used for this purpose in Europe, Japan, South Korea, and Brazil.

Drilling Muds

Because of its high density, ilmenite has at times been used as a component of drilling muds, particularly in North Sea oil drilling operations.

Product Pricing

Of the 110 elements in the periodic table, titanium ranks seventeenth in terms of global consumption by tonnage. TiO_2 is now the third top inorganic chemical behind ammonia and phosphoric acid in terms of consumption.

To establish a basis for forecasting future prices for titanium feedstocks, it is necessary to briefly examine the long-term historical trends in prices.

Rutile

Figure 3 shows prices for Australian exports of bulk rutile during the period from 1970 to 2003, in real 2003 terms and in nominal values. The prices come from the ABS export data in Australian dollar values (AUS\$) and have been converted to U.S. dollar values (US\$) using the annual average AUS\$–US\$ exchange rate.

During this period, US\$ prices for rutile have moved within a real price band of US\$400 to US\$800/t f.o.b., but show an overall declining trend of approximately 0.8%/yr in real terms. The cyclical nature of the rutile price broadly reflects the cycles in the TiO_2 pigment industry, with troughs in 1978, 1983, 1993, and 2000. Prices declined sharply from 1990 to 1993, in tandem with the global economic slowdown, reaching levels close to their historical low real values before beginning a slight uptrend. This was accelerated by market tightness triggered by the cessation of production at Sierra Rutile Limited (SRL) in early 1995. Prices have subsequently softened to more sustainable levels, in view of the fact that following the SRL closure, rutile is now regarded as a niche product relative to the dominant feedstock types.

Although it is not possible to obtain accurate prices for all ilmenite products (some of which are sold under long-term contracts negotiated some years ago), TZMI analyzed the prices of ilmenite exported from Australia for both sulfate and chloride use. Because Australian ilmenite accounts for the bulk of global trade,

this is a reasonable parameter to use in the analysis of price trends. The base data came from the Australian Bureau of Statistics.

Figures 4 and 5 show the trends in both nominal and real 2003 US\$ terms for Australian chloride and sulfate ilmenite prices, respectively, from 1975 until 2003.

The US\$ real price for 60% TiO₂ chloride-grade ilmenite shows a slightly declining trend line over the period to 1986, after which there was a 2-year transition period during which ilmenite was related to a much higher nominal level. Since 1988 there has been a trend-line growth in real US\$ prices of 1.3%. The fluctuations in recent years basically reflect a changing mix of ilmenite contracts.

Similarly, the long-term trend line for Australian 54%- to 57%-TiO₂ ilmenite for the sulfate process declined by 1.2%/yr during the period from 1970 to 1986, followed by a 2-year transition zone after which the trend-line rate has been -0.8%/yr.

It is noticeable that prices for sulfate ilmenite have historically been higher than prices for chloride ilmenite, although the TiO₂ content of sulfate ilmenites is lower than that of chloride ilmenite products. There are a number of reasons for this apparent anomaly:

- The market for chloride ilmenite is relatively narrow, with only one pigment producer (E.I. DuPont de Nemours and Co.) able to use ilmenite directly for chloride pigment production.
- The only other application for chloride ilmenite is as feedstock for SR production, but most ilmenite for this purpose is produced internally by the SR producer. The major exception is Kerr-McGee, which has for many years purchased 51% TiO₂ ilmenite from Consolidate Rutile Limited (CRL) and other sources.
- Consequently, DuPont has been able to use its considerable purchasing power to negotiate very favorable prices for chloride ilmenite.
- Average prices for chloride ilmenite have been influenced significantly by lower priced long-term supply contracts with DuPont. In particular, this applied to sales made in A US\$ terms of Eneabba ilmenite, which has relatively high U+Th content and for which DuPont is effectively the only buyer.

Recent contract prices negotiated for high-quality 60%-TiO₂ ilmenite, however, are at levels above current prices for 56%-TiO₂ sulfate ilmenite.

The rerating in the price of ilmenite, which clearly had been undervalued in comparison with other feedstocks before this date, arose for several reasons, including:

- The RGC takeover of Allied Eneabba, with a consequent increase in concentration of chloride-grade ilmenite supply
- The decision to build several SR plants in Australia, which moved some ilmenite from the traded category to the captive category
- Increased scarcity of quality ilmenite

In addition, later new operations such as Tiwest's Cooljarloo mine and Cable Sands' Jangardup mine resulted in the emergence of a wider spread of ilmenite supply. Another contributing factor was the policy decision of WSL from 1990 to purchase 60%-TiO₂ ilmenite for its Becher SR plant operations and so help prolong the life of its own resources.

As a result of these developments, the market began to play a greater role, particularly in the supply of chloride ilmenite, and prices rose accordingly.

Synthetic Rutile

The SR prices shown in Figure 6 are based on the reported value of Australian exports in AUS\$ and converted to US\$ as the source of

Figure 3. Rutile prices in real and nominal terms (1980–2003), US\$/t

Figure 4. Australian chloride ilmenite prices, nominal versus real (1980–2003), US\$/t

Figure 5. Australian sulfate ilmenite prices, nominal versus real (1980–2003), US\$/t

Figure 6. SR prices nominal versus real (1980–2003), US\$/t

Figure 7. Chloride slag prices nominal versus real (1980–2003), US\$/t

price data represents the highest proportion of total SR purchases. The chart clearly shows that since the late 1980s, real US\$ prices have fallen. This reflects the impact of currency exchange variations. SR is the only high-TiO₂ feedstock that has been sold extensively in AUS\$, mainly because Australia has dominated supply. The result of this practice, which continues today, is that although both real and nominal prices in AUS\$ terms have risen since the mid-1980s, in US\$ terms, SR prices declined as the AUS\$ devalued against the US\$. The situation developed whereby in US\$ terms, SR was considerably cheaper than would be expected for its TiO₂ content. Its price was low relative to the other TiO₂ feedstocks that are sold in US\$. In the last few years, however, as the AUS\$ strengthened considerably against the US\$, that trend reversed. As a result, the US\$ price of SR is now closer to its relative economic value.

Chloride Slag

Figure 7 shows historical chloride slag price data from U.S. import statistics. In real terms, chloride slag prices have shown very little fluctuation in price during the period from 1980 to 2003, consistently increasing at an average 2%/yr over this period, although they were basically flat for the period from 1997 to 2003. The upward price trend was the result of most slag sales being contracted on a long-term basis with escalating price provisions, as

well as the fact that RBM was the only producer of chloride slag until 1995 and so faced no direct price competition. The reduction in slag prices in 2003 is clearly evident.

Upgraded Slag

Because UGS was first produced commercially only in late 1997, comparable long-term trend lines cannot be calculated. In fact, most UGS prices in real terms did not change in the period to 2002 because of QIT's tight contract provisions.

It is highly relevant to note that several initial contracts for 95% TiO₂ UGS were originally priced in early 1996 terms at US\$480/t. The application of an escalation rate based on the U.S. Consumer Price Index (CPI) meant that the price of UGS has increased in nominal terms but remained constant in real terms.

Because of market resistance to these escalated prices, which has inhibited some sales, QIT recently prepared to reduce prices to remain competitive relative to other high TiO₂ feedstocks.

Recent Price History

To put any price projections into perspective, it is important that the recent price history for key products be noted. Tables 6 and 7 show these in nominal and real US\$ 2002 terms, respectively.

For 2003, the general pricing direction was downward, with the prices of several feedstocks coming under pressure because of persistent oversupply and more competitive market conditions, influenced by the entry of new suppliers. Other feedstocks simply continued existing downward trends. Exchange rate moves again played an important role in influencing price moves, particularly the strengthening AU\$ and its influence on SR pricing in the U.S. market. Confusing the overall trend was the coexistence of older, long-term contracts and recently negotiated new contracts, which led to tiered pricing levels for some products, particularly slag. Average prices for sulfate ilmenite fell slightly, under pressure from increasing supply, whereas average chloride ilmenite prices improved, although the higher prices reflected more widespread trade in better-quality products rather than the overall market direction. Chloride slag prices declined in 2003, with some price increases (which resulted from price-escalating clauses in existing contracts) being offset by lower prices for more recent contracts. Average bulk rutile prices fell in 2003, further extending the general decline in rutile prices since the brief surge in 1995 after SRL closed. Rutile supply progressively tightened during 2003, however, because of lower output from several major producers, and this has led to strengthening rutile prices in recent months. Higher prices are particularly evident for bagged material used in welding electrode markets.

The pricing events of 2002 and 2003 are highly relevant in TZMI's view because they herald a significant new era during which TiO₂ pigment producers will clearly exercise considerably greater influence on pricing than has been the case in the past, particularly with the Rio Tinto group.

ECONOMIC FACTORS

By-products and Coproducts

Zircon

Zircon is by far the most significant coproduct (and in some instances a by-product) of titanium mineral production and is an important contribution to the revenue of these producers. Zircon concentrations can range from as low as 0.1% in low-grade dunal occurrences to as high as 3.0% in high-grade strandline deposits. More than 70% of titanium feedstock production also generates zircon revenue, which typically accounts for between 15% and 35% of

Table 6. Annual nominal free on board (f.o.b.) prices of selected titanium products (1998–2003), US\$

Titanium Product	1998	1999	2000	2001	2002	2003
Sulfate ilmenite	74	87	85	87	81	80
Chloride ilmenite	65	75	69	66	75	78
Rutile	490	458	463	462	442	409
Synthetic rutile	329	330	336	293	313	375
Sulfate slag	307	307	320	325	335	337
Chloride slag	387	400	410	415	420	397

Table 7. Annual real f.o.b. prices of selected titanium products (1998–2003), US\$

Titanium Product	1998	1999	2000	2001	2002	2003
Sulfate ilmenite	83	96	90	90	83	80
Chloride ilmenite	73	83	73	68	76	78
Rutile	552	506	494	479	452	409
Synthetic rutile	371	365	359	304	320	375
Sulfate slag	346	339	342	337	342	337
Chloride slag	436	442	438	431	429	397

total mineral production revenue and in some operations is as high as 50%. Zircon is therefore fundamental to the economic success of many titanium mineral producing operations. This coproduct is covered in a separate chapter within this volume.

Garnet

Garnet can be an important coproduct for mineral sands operations. Several mineral sands operations on the east coast of India are in fact mining garnet, and the titanium-bearing minerals are considered to be a by-product. Recent expansion and upgrading work at some of these operations has improved the separation of ilmenite from the waste stream, leading to its sale as a commercial product. Garnet from mineral sands mining is used in water-jet cutting, filtration, and abrasives applications.

Sillimanite

Sillimanite is a by-product of mineral sands mining in regions where the mineral sands were derived from the erosion of metamorphic basement rocks—the west coast of India, in particular. Sillimanite and its polymorphs—andalusite and kyanite—are used principally in the refractories market. When calcined, sillimanite and its polymorphs convert to a mixture of the very high temperature refractory mineral mullite and free silica. Mullite is particularly valuable in the refractory industry because it forms interlocking crystals that are stable up to 1,800°C, making it an excellent material for lining furnaces.

Monazite

Monazite is a rare-earth phosphate mineral that accumulates in mineral sands deposits owing to its high specific gravity. Its high content of the element thorium gives this mineral substantial natural radiation, which has limited its use since the 1990s. In the past, monazite was a sought-after mineral because of that high content of thorium (approximately 3% to 9% ThO₂). Thorium's main use was in gas light mantles, where the presence of thorium compounds produced a high incandescence at extremely high temperatures without melting, which made thorium gas lamps much brighter than ordinary gas lamps. The expansion of modern electric light has caused a decline in this application, which has been restricted in

developed economies to use in camping equipment. Even this application has fallen away in recent years, however, from the perceived danger from radiation. Most gas mantles produced today are made with yttrium.

Monazite is now most commonly used as a source of rare earths. The rare earths have found a niche market in high-technology applications such as permanent magnets, nuclear magnetic resonance, and catalysts for the automotive industry, among others.

Pig Iron

High-purity pig iron (HPPI) is an increasingly important coproduct to the titanium minerals industry, particularly as the production of titanium slag increases in line with industry demand for higher TiO₂ feedstocks. HPPI is typically sold at a much lower price than titanium slag; however, revenue from iron can represent 20% to 25% of the revenue from titanium feedstocks. HPPI is used within the steel industry as a high-quality source of iron, where it commands higher prices than conventional iron products. The market for HPPI in recent times has been strong, with high prices owing to an increase in demand for steel from China.

OUTLOOK AND FUTURE TRENDS

Supply/Demand Fundamentals

The TiO₂ pigment industry has generally been cyclical in nature, and the status of the market for titanium feedstocks at any point in time depends on these cycles. The trends in demand for feedstocks, however, do not mirror exactly the trends in pigment consumption, despite the pigment production industry consuming 93% of annual off-take in 2003. This arises because of the long distribution chain between pigment producers and the final consumption of pigment. The accumulation of stocks in this chain causes the market impact on demand for feedstock to lag behind the market trends for pigment consumption.

Forecast titanium feedstock demand is built up as follows. Short-term pigment consumption growth is estimated from an analysis of forecast economic growth on a regional basis. The historical correlation between gross domestic product (GDP) growth and pigment consumption is used to give a broad estimate of future pigment consumption growth. Available industry forecasts of TiO₂

Table 8. Global titanium feedstock supply/demand balance (2001–2005), thousand TiO₂ units*

Consumption/Production	2001 [†]	2002 [†]	2003 [†]	2004 [‡]	Year-on-Year, %	2005 [§]	Year-on-Year, %

** Chloride fines are that portion of chloride slag production for which the particle size is too small to be successfully used in the chloride process. It is usually used as a supplementary feedstock for sulfate process plants.

pigment consumption in the major market segments of coatings, plastics, and paper supplement this analysis.

For 2003, pigment consumption was estimated using complete data for virtually all the major consuming countries. Individual pigment plant capacities come from reported capacity at the end of 2003, with adjustments for announced changes in capacity and additional forecast changes estimated by TZMI.

The annual estimates of global pigment production from 2004 onward were allocated plant by plant, based on assessed production levels for 2003, expected changes in production, and adjusted for forecast changes in capacity.

Feedstock demand is estimated for each product, based on the assessment of consumption of individual products by each individual pigment plant in 2003. To calculate future feedstock consumption, adjustments were made to the product mix in those cases where the 2003 data were considered to be abnormal or known changes were foreshadowed. This adjusted feedstock consumption mix then was prorated by the individual pigment plant's forecast production to determine forecast consumption for each feedstock product on an individual plant basis. These individual plant forecasts are totaled for each major consumer or groups of minor consumers.

- Future titanium sponge production was forecast on a global basis using industry forecasts (from both producers and industry associations such as the Japan Titanium Society) for future

titanium metal demand. This global production was allocated to individual titanium sponge producers based on historical performance and expected changes in production capabilities.

- Forecast demand for feedstocks for titanium sponge production was estimated in a similar manner to the demand for feedstocks for pigment production, plant by plant.
- The growth in demand for feedstocks for welding electrodes and other applications was estimated using general economic trends and industry data. These trends were applied in calculating forecast feedstock consumption by product.

Table 8 gives the estimated supply/demand balances for 2001 through 2005. Although every effort is made to provide the most accurate information possible, the margin of error on this analysis is estimated at about 50,000 TiO₂ units, and the supply forecasts do not include any adjustments to inventory levels.

Higher production is forecast for 2005 for feedstock products with the exception of SR and sulfate slag. For SR, all plants are already operating at capacity. For sulfate slag, there is significant oversupply at present. The oversupply is reflected in the decision of one major producer of titanium slag to schedule a prolonged shutdown of its smelter in 2005, resulting in overall lower levels of supply.

TZMI forecasts indicate that supply and demand for titanium feedstocks will be closely balanced in 2005. After 1 year of strong

pigment consumption growth in 2004 and further growth of about 3.0% to 3.5% in 2005, a need for higher levels of slag production is expected, with some suppliers that have been operating at reduced capacity in the past few years progressively returning to full capacity by 2006. Although overall demand is expected to continue to grow at average rates of just under 3.0%/yr, the additional slag production and new supplies of rutile and ilmenite from new projects in 2006 should return both chloride- and sulfate-grade feedstocks to an oversupplied position from 2006.

The Longer-Term Market Outlook

Figure 8 shows TZMI's assessment of the likely supply/demand scenario through to 2008. The analysis indicates the possibility for the titanium feedstock market to be oversupplied through to 2010, based on additional supply from both approved new projects and selected likely feedstock projects. These projections are based on the assumption that demand for titanium feedstocks continues to grow at approximately 2.9%/yr during this period, while supply from existing operations remains static and, in some instances, declines because of resource depletion or lower grades. The approvals in 2004 for new projects such as Kenmare Resources' Moma project, Iluka Resource's Douglas project, and Bemax Resources' Poona project, however, will add considerably to future supply, and greatly reduce the size of the potential supply gap.

A considerable number of new projects are being evaluated. Clearly, there is not room in the market for all of them to proceed to development in the time frame indicated, and only a select few will ever reach production stage. In Figure 8, TZMI therefore estimated total supply from "likely" new projects (without naming individual projects), and this is depicted as the shaded area in Figure 8, representing approximately 350,000 T iO₂ units of new supply at its peak. Of considerable strategic importance is which project or projects are developed first, because this will influence the availability of individual feedstock products and affect the subsequent development of other new projects by further altering the dynamics of the potential supply gap.

Strategic Issues

The titanium feedstock industry is highly concentrated and therefore dominated by relatively few companies at both ends of the supply chain. Just two companies are responsible for almost 50% of global titanium feedstock supply, and just three companies possess more than 50% of installed T iO₂ pigment production capacity. Clearly the relationships that develop between these large suppliers and consumers of T iO₂ feedstocks can have a significant effect on the titanium feedstock industry as a whole. In particular, the actions that the industry leaders take to maintain or exchange their respective positions have implications for the entire industry.

It is in the interests of the major feedstock consumers that new titanium feedstock projects receive approval, because the increased supply will flow on to more competitive pricing of titanium feedstocks. In turn, feedstock producers must rely in part on off-take agreements to gain approval for developing new projects through to commercialization. The titanium feedstock industry is therefore in the difficult position of effectively handing control of future pricing of their products to their consumers, which could have implications for future profitability of the titanium feedstock industry.

Figure 8. Global titanium feedstock supply/demand balance (2001–2005)

The influence of China is another important strategic issue for the industry. China recently emerged as a significant force in the titanium industry. In 2003, for the first time, China surpassed the United States as the world's largest titanium pigment importer, importing more than 250,000 t of T iO₂ pigment compared with just 100,000 t in 1999. Since 1999, consumption and production of T iO₂ pigment in China have both more than doubled. China does not yet have access to the chloride process of T iO₂ pigment production, the technology for which is tightly controlled by existing producers. Nevertheless, it is simply a matter of time before the technology is introduced there. This is particularly relevant given the current push for tighter environmental standards for industry in China. Many of the existing sulfate plants do not operate within existing environmental standards. Tighter regulations might embargo further expansion of sulfate route pigment production capacity. Western sulfate pigment producers have developed efficient waste management and coproduct streams to comply with tightened environmental regulations while remaining cost-effective. If China seeks to further increase its pigment production capacity without chloride route technology, there may be an increased focus on the use of high-T iO₂ feedstocks. This has the potential to dramatically alter the dynamics of the global titanium feedstock industry.

Tripoli (Microcrystalline Silica)

William A. Bratney

Tripoli is an industrial mineral commodity important to many market sectors, including the paint industry, in which it performs as a chemically inert, very fine-grained extender. In the plastics, rubber, adhesives, and sealants industries, it serves as a functional filler imparting strength, opacity, and other beneficial properties. Because of its uniform size, mineral hardness, and orientation of the crystal faces, the abrasives industry uses tripoli as a buffing and polishing compound.

Microcrystalline silica is a better name than tripoli for this soft, porous, siliceous material, because it describes the physical and chemical characteristics of the material. In this chapter, microcrystalline silica is used in preference to tripoli for most of the discussion. The term *tripoli* is still the appropriate term for microcrystalline silica that is used principally as an abrasive.

Microcrystalline silica consists almost entirely of extremely small quartz crystals, many of which are less than 1 μm long. Three companies produce microcrystalline silica in the United States, all from open-pit mines. The ore is beneficiated by crushing, grinding (often to a micronized particle size), and sizing. All the active operations are located in the central part of the United States. Important prospects exist in other countries, and it is reportedly produced for export in China (C.T. Steuart, personal communication). Physical and chemical differences among the active deposits exert a strong bearing on the markets served, especially natural grain size, color and brightness, impurities, ease of disaggregation, and product porosity.

DEFINITIONS

Tripoli

Tripoli is the historical term for microcrystalline silica used principally in abrasives applications. It is an extremely fine-grained, generally friable, and porous rock that consists almost entirely of submicroscopic quartz crystals, most of which are less than 2 μm long. Some deposits of this microcrystalline quartz may form as a result of the hydrothermal alteration of a chert-bearing limestone, while others may originate through deep weathering of an originally siliceous limestone with solution and removal of calcite and the introduction of and recrystallization of quartz. The term tripoli has been used and, in some instances, continues to be used interchangeably with microcrystalline quartz. Both the rock and the commercial material derived from it are best described as microcrystalline silica. Historically, in the United States the term tripoli was first used to describe the fine-grained, easily disaggregated

material from Seneca, Missouri, because of its similarity to a rock from the Tripoli region of North Africa (Hovey 1894). Missouri and Oklahoma material is also sometimes called tripolite (Quirk and Bates 1978). Other deposits of microcrystalline silica, such as those in southernmost Illinois, later came to be known as tripoli. The North African tripoli rock, however, is actually diatomaceous earth, or diatomite, a material that is similar in macroscopic appearance to the rock from Seneca, Missouri, but is of entirely different origin, having formed by the accumulation of the siliceous remains of microscopic marine or freshwater golden algae, or diatoms. The essential difference between diatomaceous earth and microcrystalline silica is that diatomite is composed of opaline (and therefore amorphous) silica rather than crystalline silica. Microscopically, the shape of the diatoms and their open internal structure are distinctive and important criteria in the use of diatomite as filtration media, a market area for which microcrystalline silica is unsuitable.

Microcrystalline Silica

The distinction between the use of the terms microcrystalline silica and tripoli is dictated largely by convention and markets. Material produced from the southern Illinois deposits is used widely in filler and extender applications, and it is generally referred to as microcrystalline silica. That material used as an abrasive buffing or polishing material, both from the Illinois district and from other states, is commonly called tripoli.

Novaculite

Although originally used to describe a rock suitable for the manufacture of whetstones, novaculite is now defined more generally as a homogeneous, mostly white or light-colored rock, translucent on the thin edges, with a waxy or dull luster, and composed of almost entirely microcrystalline quartz (Steuart, Holbrook, and Stone 1983). The more compact rock mined in central Arkansas from the Arkansas Novaculite is referred to as novaculite, whereas the more porous and friable rock is referred to as tripoli or tripolitic novaculite.

Amorphous Silica

Amorphous silica, as an industrial term, was once used to describe the material produced from the deposits in southern Illinois. It has been replaced by the term microcrystalline silica. The term amorphous silica came into use at a time when optical methods for the identification of very fine-grained quartz were not widely available,

Figure 1. SEM photograph of material from American Tripoli, Inc. It is known as Seneca Standard tripoli.

Table 1. Tripoli production and value data

	1998	1999	2000	2001	2002
Production, t	79,600	84,900	72,000	60,500	66,600
\$ Value (× 1,000)	16,900	20,200	15,900	15,000	16,600
\$ Value/t	212	238	221	248	249

and the Illinois product, composed of quartz grains too small to be seen with the unaided eye, was thought to consist of amorphous silica. The material mined in the midcontinent region of the United States is clearly crystalline quartz, as shown by x-ray diffraction (XRD) analysis and scanning electron microscopy (SEM; Figure 1).

Opal

Opal exists in three forms: opal-A, opal-C, and opal-CT. It precipitates from sea water or fresh water as an amorphous gel (opal-A) with its composition being between 3% and 10% or more of water. Over time, through diagenesis it can transform into opal-CT (an opal showing the beginning of formation of domains of short-range ordering similar to the arrangement of atoms in extremely fine grained cristobalite and tridymite) or into opal-C, then to chalcedony (fibrous microcrystalline quartz), and then to macrocrystalline α -quartz. Morganite, a microcrystalline monoclinic polymorph of quartz, first described by Flörke, Jones, and Schmincke in 1976 and named in 1984, is widespread in microcrystalline quartz varieties and is being identified more frequently in this transitional sequence from amorphous silica to quartz. The process is marked by progressive reductions in the porosity of the deposited silica and its water content, and a consequent increase in its density. The instability of the attached water molecules gives opal its tendency to crack or decrepitate at high temperatures. Opaline silica makes up the bulk of the silica in economically important diatomaceous earth deposits and also forms in hot springs environments, in association with crystalline silica, as geyserite or siliceous sinter.

Related Terms

Other common varieties of microcrystalline silica are chert, chalcedony, jasper, and flint. The crystalline structure of chalcedony is unique in that the quartz can be fibrous or porous, but still the mate-

rial is considered to be crystalline, and quartz can be recognized by XRD analysis.

Chert, chalcedony, jasper, and flint are interchangeable terms for hard, very fine-grained microcrystalline silica. This material is extremely dense, breaks with a conchoidal fracture, and has been used throughout history for edged weapons such as knives, spear points, war clubs, and arrowheads. Close inspection reveals this form of silica to be composed of tightly interlocking quartz crystals of less than about 30 μm in diameter. It may also contain amorphous silica.

Ganister is a term for a high-silica, friable rock that is marketed in irregularly sized pieces, and that is an inch or less in size; it is used in the manufacture of silica brick (Lamar 1953). The color of this material is usually white or cream, but it may be stained to red, orange, or yellow by iron oxides without adversely affecting its industrial application.

The commodity known as *rottenstone* is sometimes included within the general mineral commodity category of tripoli. Rottenstone is mined in Northumberland County in eastern Pennsylvania, and it is formed by the weathering of siliceous shale of Devonian age (Faill 1979). This material is used as a filler and extender in certain applications, but it is unlike tripoli both in origin and physical properties.

Spiculite is a rock consisting of siliceous sponge spicules that formed by the removal by solution of the carbonate matrix of a spicule-bearing limestone. Spiculite has been mined in Texas and, because it resembles tripoli in several aspects, it is included in the discussion of deposits.

PRODUCTION AND TRADE, RESOURCES AND RESERVES

Sales and Exports

Information compiled by the U.S. Geological Survey (USGS) *Minerals Yearbook* staff (Dolley 2002) shows that sales of tripoli and silica-rich rottenstone from Pennsylvania amounted to 66,600 t in 2002. This represents an increase of approximately 10% over the 60,500 t processed in 2001. Table 1 gives tripoli production and value data between 1998 and 2002 (Dolley 2002).

A USGS annual survey of producers (Dolley 2002) indicated that the output of crude tripoli produced domestically in 1995 was 79,700 t with an estimated value of \$3 million. In the United States, four firms are known to produce or process tripoli. Malvern Minerals Company, in Garland County, Arkansas, produces crude and finished material. Malvern also produces a black material from novaculite. American Tripoli Company produces crude material in Ottawa County, Oklahoma, and finished material in Newton County, Missouri. Unimin Specialty Minerals Inc. in Alexander County, Illinois, produces crude and finished material. Keystone Filler and Manufacturing Company in Northumberland County, Pennsylvania, processes rottenstone. This company has been in operation for 60 years. It purchases the mined rottenstone and processes it by grinding into a product that is 99% –325 mesh for the brake-liner industry.

In prior years, the production and consumption of microcrystalline silica (including tripoli) products ranged from an average of 35,864 t for the years 1951–1955 (Chandler and Tucker 1961) to 105,220 t in 1979, the year of maximum sales (Anon. 1981). In 1979, the sale of microcrystalline silica for use in the filler and extender markets exceeded the sale of tripoli for the abrasives industries.

Tripoli has unique applications as an abrasive because of its hardness and because its grain structure lacks distinct edges and corners. It is a mild abrasive, making it suitable for use in toothpaste and tooth-polishing compounds, industrial soaps, and metal/

jewelry polishing compounds. The automobile industry uses it in buffing and polishing compounds for lacquer finishing. The end-use pattern for tripoli has changed significantly in the past 25 years. In 1970, nearly 70% of the processed microcrystalline silica was used as an abrasive in various tripoli products. Kelley, Dolley, and Olson (2004) charted tripoli production and sales statistics for use in the abrasives industry through 2002. In 1989, almost 2.5 times as much of this commodity was used in filler and extender applications than in abrasives (Austin 1992). In 1995, more than 75% of microcrystalline silica output was used as a filler and extender in paint, plastic, rubber, caulking compounds, and enamel. The best grades of microcrystalline silica are used as fillers and extenders in paints. These applications may account for as much as 85% of the microcrystalline silica used as a filler and extender. The average reported value of all microcrystalline silica sold or used in the United States was \$131/t in 1995, slightly less than its value the previous year. The average reported value of abrasive tripoli sold or used in the United States in 1995 was \$151/t (Balazik 1995).

Foreign competition has not been a significant factor in these markets because significant production is largely confined to the United States (Harben 1983). The United States is an exporter of Tripoli; export from the Missouri–Oklahoma District was reported as early as 1894 (Fellows 1967). Foreign markets for microcrystalline silica continue to be important. For instance, Arkansas tripoli, in addition to supplying domestic customers, is exported to Canada, Taiwan, most of Europe, Israel, Turkey, Australia, New Zealand, the Republic of South Africa, Saudi Arabia, and South America.

TRIPOLI DISTRICTS

All the commercial deposits of microcrystalline silica in North America occur in three districts in the central and southern United States. They include the deposits in southernmost Illinois, the tripolitic novaculite mines of central Arkansas, and the Missouri–Oklahoma tripoli district. Textural differences exist between these deposits, but there are many similarities in geologic setting. Deposits of tripoli also have been described in Alabama, Georgia, Mississippi, and Tennessee. These occurrences are currently undeveloped and were mined originally as local sources of abrasives and polishing compounds. Siliceous sponge spicule accumulations were mined in the past in Texas for use in special drilling muds.

Southern Illinois District

Illinois has been the site of major microcrystalline silica production since the early 1900s. The first reported shipments were before 1906, and Bain (1907) reported three mills in operation at that time. At least nine companies have produced microcrystalline silica from the many small deposits in Union and Alexander counties in southernmost Illinois (Berg and Masters 1994). Unimin Corporation purchased Tammsco in 1987, and then acquired Illinois Minerals from Georgia Kaolin 2 years later. Unimin Specialty Minerals Inc. operates the McCrite-Birk open-pit mine in Alexander County, which supplies tripoli to the processing plant in Elco. The Tamms plant is now used as a grinding facility for other Unimin Corporation mineral products. Other occasional production in the district comes from Lone Star Industries' mine, where off-color microcrystalline silica and chert are produced for use in its portland cement plant at Cape Girardeau, Missouri. Unimin Specialty Minerals Inc. regularly supplies iron-stained microcrystalline silica and chert from its overburden stripping and from off-color interbeds within the mine to several cement producers in the midcontinent region.

The southern Illinois tripoli district lies a few kilometers west of the small town of Elco. The silica-rich rocks encompass approximately 150 km² in Alexander and Union counties. This area con-

tains well over 100 inactive underground mines and prospect pits. There are also several inactive mines in the Wolf Lake Area, about 17 km northwest of Elco.

Microcrystalline silica deposits are located within a Devonian stratigraphic sequence exposed along a north-south trending belt on the southwestern margin of the Illinois Basin. Mississippian-aged sedimentary rocks are exposed east and northeast of the district, and Ordovician and Silurian units crop out to the southwest along the Mississippi River. The Lower Devonian Clear Creek Chert hosts the active mines. Outside of the tripoli mining area, the Clear Creek Chert is a dolomitic limestone containing chert interbeds; but within the district, carbonates are not found within this formation and silica has been introduced. The Clear Creek Chert is a 60- to 90-m-thick mixture of chert beds, decomposed, friable, variably colored to white microcrystalline silica beds, and fossiliferous thinly bedded chert layers. The Backbone Limestone, the unit lying immediately beneath the Clear Creek Chert in other parts of the southern Illinois region, is not found in the tripoli district, presumably because it has been removed by solution. The Grassy Knob Chert directly underlies the Clear Creek Chert, and it consists of massive chert beds near the mines, becoming less cherty with depth near the contact with the Lower Devonian Bailey Limestone. The Clear Creek Chert is overlain unconformably by the Dutch Creek Sandstone Member of the Grand Tower Limestone. This unit is a tan to off-white, silica cemented, medium- to coarse-grained, massively bedded sandstone, 0 to 3.0 m thick in this area.

In the Elco District, the uppermost 20 to 30 m of the Clear Creek Chert consists of massive chert beds that cap narrow, flat-topped ridges between deep hollows (Levine 1973). Beneath these chert beds, thinly bedded (less than 30 cm thick), prominent, hard chert beds are interbedded with softer chert and friable microcrystalline silica. Commercial beds of microcrystalline silica range from 2.4 to 12.2 m thick (Berg and Masters 1994). The best material is strikingly white, but cream to buff lenses are also mined. Sunglasses are strongly advised when visiting the open-pit mines. Poor-quality material occurring within the mining horizon is carefully stripped during development and is stockpiled for use as cement kiln feedstock throughout the region. The McCrite-Birk mine occupies more than 10 ha, and it is by far the largest tripoli mine developed to date. Bedding in the mine is typically close to horizontal, but it is impossible to follow the individual layers more than a few tens of meters. This is due to the abundant near-vertical joints and also to the many high-angle faults with offsets of only a few centimeters to more than 5 m. These structures are often filled with gray kaolinite clay and are typically bounded by strongly iron-stained material. Shrinkage resulting from volume reduction—caused by the removal of the original carbonates—is believed to be responsible for the numerous structures in the deposits.

The origin of the southern Illinois tripoli deposits is complex. The presence of brachiopods, trilobites, and other marine fossils preserved in many of the hard chert layers and associated with the bright white microcrystalline silica zones, coupled with the existence of carbonates in adjacent parts of the Illinois Basin, requires a mechanism to not only remove essentially all of the original carbonate material but also introduce abundant silica to the formation while aggressively bleaching the rock to its current whiteness. Berg and Masters (1994) and other geologists believe that deep in-place dissolution of the carbonates may have been caused by circulating convective hydrothermal systems driven by heat from mafic plutons emplaced within the Precambrian basement. A distinct magnetic anomaly exists west of Tamms and Elco, and another one has been mapped below the Wolf Lake deposits (Heigold 1976). The hot waters bleached the rock, and they carried dissolved silica, which

was precipitated as euhedral, microscopic quartz crystals, in the voids created by the solution of the carbonate beds.

Missouri–Oklahoma Border District

Seneca, Missouri, has been an important center of tripoli production for more than 100 years (Dobbs 1960). Discovered in 1869, tripoli was first mined in 1871, and the first grinding mill was constructed in 1885. The American Tripoli Company was formed in 1888, and it continues to produce a wide range of microcrystalline silica products today as American Tripoli Inc. Deposits exist in Newton County, Missouri, and in Ottawa County, Oklahoma. Now mining is limited to exposures southeast of Peoria, Oklahoma, although inactive mines exist along the border between the two states and northeast of Seneca, Missouri.

Tripoli in the Missouri–Oklahoma border district occurs in bedded units of the Warsaw Formation and, to a lesser extent, in the underlying Burlington-Keokuk Limestone. Both formations are Mississippian in age. Tripoli is confined to these two formations, but the deposits do not seem to be limited to specific stratigraphic intervals within them. Cherty limestones host all of the deposits, which are thin, and range between 1.3 and 6.6 m in thickness. The mines are all open-pit operations, and overburden is typically less than 3.3 m of red clay, chert, and impure tripoli (Fellows 1967). A flint-like caprock overlies some deposits. The lateral extent of individual deposits tends to be small, generally a few tens of meters across. In contrast, a deposit south of Peoria, Oklahoma, encompasses approximately 3.6 ha. Deposits occur on broad, flat-topped hills in the region. The color of the tripoli ranges from cream to rose, depending on the iron content. The rose tripoli contains more alumina, iron oxide, and titania than do the cream deposits. The concentration of chert nodules within the deposits is important, because if they are too abundant the deposit cannot be processed into an acceptable product. Secondary silica has been deposited along some of the steeply dipping fractures in the deposits.

Several explanations have been offered over the past 90 years to account for the origin of the Missouri–Oklahoma tripoli deposits. All of them include the removal by solution of some of the carbonate material from the sedimentary rock to form the tripoli. Quirk and Bates (1978) suggested that beds formed by the deposition of colloidal silica and alkali salts were subsequently attacked by weathering processes, which removed the salts and concentrated the silica. This explanation follows the earlier formation hypothesis of Siebenthal and Mesler (1908), who suggested that the original rock was a siliceous limestone from which all of the carbonate had been dissolved, resulting in a local concentration of tripoli. Using acid, they dissolved a siliceous limestone to produce a poor grade of tripoli. The volume reduction from this process was extreme. It has not been possible to trace laterally a bed of tripoli into fresh, unaltered rock, and surprisingly no fossils or relict bedding structures can be identified in the tripoli deposits. Siebenthal and Mesler (1908) mentioned the occurrence of cherty slickensides within some of the tripoli deposits, which suggests that secondary silica was introduced into fractures produced by volume reduction along which there was renewed movement.

A third explanation, presented by Perry (1917), calls for the extensive weathering of a thick homogeneous chert bed. About 3 km north of a tripoli deposit, a persistent chert bed is exposed in approximately the same stratigraphic position. The outer margins of the tripoli deposits are always observed to grade into chert. Scanning electron micrographs of chert from these deposits show a tripolitic rim on hard chert cores, indicating that at least some of the tripoli formed by the alteration of chert (Keller 1978).

Arkansas Tripolitic Novaculite District

Tripoli mined from the Arkansas Novaculite is a homogeneous, white to tan, mostly poorly to well cemented, friable rock, composed almost entirely of microcrystalline quartz (Berg and Steuart 1994). Novaculite was first mined near Hot Springs, Arkansas, in the eastern Ouachita Mountains from a very hard, white, siliceous rock for use as sharpening stones (Holbrook and Stone 1978). Griswold (1892) described the fine-grained whetstone known as the Arkansas Stone as a "true novaculite satisfying all the necessary conditions regarding homogeneity, grittiness, finely granular structure and siliceous composition; it is translucent on the edges and has a marked conchoidal fracture." Keller, Vele, and Johnson (1977) proposed that the word novaculite be used to describe only a thermally metamorphosed chert that shows polygonal triple-point structure.

Tripolitic novaculite is restricted to the Upper Division of the Arkansas Novaculite, and Hass (1951) identified it as early Mississippian in age, based on his study of a conodont fauna at Caddo Gap, Arkansas. The Upper Division of the formation is thickest in the vicinity of Hot Springs and thins rapidly to the north and more gradually to the south and west. Recognizable beds vary in thickness from several centimeters to 1.3 m. Not all of the Upper Division rock is tripoli bearing. Much of it is calcareous, appearing variably weathered to light brown or buff rotten rock with a gritty texture. Weathered novaculite varies from a firm, slightly porous rock, which looks much like a siltstone, to soft Tripoli, depending on the amount of carbonate present in the original rock. The carbonates found in fresh rock amount to as much as 30% and consist of calcite, mangiferous calcite, rhodochrosite, or ankerite. These tripoli deposits attain thicknesses of more than 33 m. Particle sizes range from 0.5 to 10 μm , and individual grains are equidimensional. Color ranges from white through lighter shades of tan and brown, depending on the quantity of iron and manganese oxides and clays present.

Charles Steuart (personal communication) points to structural preparation as the most important reason for the development of commercial deposits of tripoli within the Upper Division of the Arkansas Novaculite. Every good locality is related to the intersection of two or more high-angle faults and, interestingly, all of the good tripolitic novaculite is mined from overturned beds. Originally the tripoli in the Arkansas Novaculite was deposited by direct precipitation of silica by chemical or biogenic means. In all likelihood, deposition occurred in a deep-water oceanic environment well beyond the limit of detrital debris. Radiolarian ooze and direct silica precipitation from seawater enriched in silica built up nearly pure accumulations in some areas as well as impure zones contaminated with carbonates. Regional metamorphism in the Ouachita Basin transformed the original sediment into chert, and subsequent extensive weathering along faults and in zones of significant carbonate minerals produced the commercial tripoli deposits.

Other Deposits

Large, noncommercial microcrystalline silica deposits are found in the northwestern part of Alabama. They have been formed by deep-seated dissolution of Mississippian chert-rich siliceous carbonate rocks of the Fort Payne Chert. Silica from dissolved chert was precipitated in the voids by circulating groundwater to form euhedral quartz crystals between 1 and 4 μm long. This material resembles the southern Illinois tripoli in texture and chemical purity. The color of the northwestern Alabama microcrystalline silica ranges from white to very pale orange. The deposits are typically 0.3 to 1.2 m thick, but some occurrences up to 24 m thick have been noted (Rheams and Richter 1992). In northeastern Alabama, smaller silica

beds are found in the Fort Payne Chert and in the Cambrian-Ordovician Chepultepec and Copper Ridge dolomites. Microcrystalline silica and tripolitic material from this area range in color from white to very pale orange and pinkish gray and in grade from fine grained powdery tripoli to coarse material with abundant chert. The friable microcrystalline silica is found in beds from about 1 m thick to one exposure 30 m thick. Production from northeastern Alabama occurred between the early 1900s and the 1920s, but there is no activity today.

Impure microcrystalline silica deposits (termed tripoli in the literature) similar to those in Alabama occur in Tennessee and in the northeastern corner of Mississippi. These deposits have been mined in several areas. The Wayne County, Tennessee, occurrences have been thoroughly described (Spain 1938; Born 1936) and probably have the greatest potential for economic development. The Fort Payne Chert hosts the tripoli deposits, which reach 20 m thick. The color of the tripoli is typically white with some brown streaks attributed to secondary iron oxides. The texture of the Tennessee tripoli ranges between compact and more friable material. The origin of these deposits is believed to be the result of preferential dissolution of the carbonate portion of siliceous limestones along structural lineaments, accompanied by the mobilization of dissolved chert and its reprecipitation (Rheams and Richter 1992). The role of the lineaments, recognized in high-altitude aerial photographs, is that they were important in channeling the flow of groundwater that dissolves the carbonates and controls the redeposition of the silica.

Other noncommercial microcrystalline silica deposits occur in Georgia, where minor production is documented north of Atlanta (Crickmay 1937). Texas also has a friable silica deposit, but it is composed of sponge spicules. Dietrich and Lonsdale (1958) described the spiculite deposits of central Texas. Calcite was leached at depth from the Pennsylvanian-aged Marble Falls Formation, leaving a rock composed of siliceous sponge spicules. Except for some residual clay, the spiculite deposits are essentially pure silica. Harris (1989) describes a small Tripoli occurrence located near Hartville in Platte County, Wyoming.

In Europe, tripoli is mined near the small town of Castro Urdiales in the Cantabria Province of Spain. Castro Urdiales is on the Bay of Biscay and near the towns of Santander and Bilbao. Tierras Industriales Herranz y Diez S.A. produces approximately 5,000 t of microcrystalline silica each year for use in filter media and abrasives. The deposit originated from the leaching of Mesozoic chert-rich limestones (R. Garcia, personal communication).

There is a tripoli deposit in the Kastorenskiy District in the Kursk region of the Russian Federation. It is reportedly located on the border with the Voronezh region, 10 km from the center of the Kastornoe District. A joint-stock company, Blagodatenskiy Building Materials Factory, has been formed to exploit the tripoli deposits for use in the manufacture of lightweight silica brick in a factory built in the 1940s. The unique chalk and tripoli deposit at Kotovo-Gudovskoe is situated on 101 ha, including the 36 ha of the existing chalk and tripoli pit. Another Russian tripoli deposit is near the town of Alaty, south of Cheboksary in the Chuvash Republic, a sovereign republic in the Russian Federation about 650 km east of Moscow. The tripoli here is mined for use in the manufacture of heat insulation materials.

EXPLORATION AND DEVELOPMENT

In the early years of the southern Illinois tripoli district, new deposits were identified simply by finding outcrop exposures of white material in steep erosional cuts in the many drainages. Exploratory adits, usually less than a few tens of meters long, were

driven into the steep slopes, and mines were developed when it was apparent that a deposit of sufficient size to justify development had been discovered. The district has many exploration openings and many small, abandoned room-and-pillar mines. Because of the small size of the deposits in this area, successful mine development was most likely limited to 10% of the exploratory adits. In recent years, drilling, diamond core, reverse circulation, and standard air rotary techniques have been used to locate and develop new deposits. Initially, exploration is conducted along the narrow ridge crests with a series of widely spaced holes until a significant thickness of white microcrystalline silica is discovered. Additional holes are completed on a tightening, irregularly developed grid along the ridge and on one or more drill trails constructed on the flanks of the ridge. Holes are spaced approximately 30 m apart before stripping the overburden to provide enough confidence of the continuity and quality of the deposit. When there are quality concerns or when mine development is approaching the edge of a drill-defined deposit, the drilling grid may be tightened to ensure that there is no unnecessary stripping.

Today, all mining in the Illinois microcrystalline silica district is conducted in open-pit operations. Samples collected during exploration and mine development drilling are evaluated in Unimin Specialty Minerals' Elco Plant Laboratory. The samples are obtained from open-air rotary holes that are blown clean after each 0.6 m of drill advance. The samples are bagged and placed in a line at some short distance from the hole. The geologist determines the sample increments for laboratory testing, prepares the samples, completes the drill logs, and retains small samples of each increment in permanent plastic chip trays. Particular attention is given to noting the hardness and chert content as well as the presence of clay in each sample. The color of the material in the drill samples is logged as well, particularly for iron- or manganese-stained material. Each drill-hole site is surveyed using modern global positioning system (GPS) equipment. At the laboratory, the samples are dried, crushed, split, and pulverized. Data are collected and reported for the Hunter L, a, b color parameters, and also the GE brightness value is determined. This information is added to the deposit database, the geologic model is revised, and the mine plan is updated. Geologic cross sections guide the annual stripping program, and the operations staff in the mine make daily development decisions using the quality data portrayed on the cross sections.

Deposit development, mining, and transport of southern Illinois microcrystalline silica is a simple affair. Overburden is drilled and blasted and placed on stockpiles constructed around the deposit, or it is backfilled into nearby exhausted open-pit mines. When the white microcrystalline silica ore zone has been uncovered, a bulldozer rips the soft material and pushes it into stockpiles. The bulldozer operator is the primary grade-control person for the entire operation. He or she determines, through experience and discussions with the mine superintendent, which material should be considered as ore and which must be treated as waste because of color or chert content concerns. The ore-grade tripoli is loaded into over-the-road trucks and is transported by improved gravel and paved roads to the plant at Elco, a distance of 8 to 14.5 km, depending on the route selected.

MARKETS

Important industrial markets for tripoli products exist in the historical abrasives sector, and newer applications have been recognized and exploited for a wide range of microcrystalline silica products in the paint, rubber, plastics, and resins industries. Minor microcrystalline silica uses include caulking compounds, refractory bricks, and cements.

Figure 2. SEM photograph showing the textural features of Malvern Minerals' L-337 Novacite product. This material is not as finely ground as the tripoli in Figure 1 or Figure 3, and it does not tend to form grain aggregates of small clumps in the same way as other materials.

Tripoli continues to have unique and valuable uses as an abrasive agent. Polishing and buffing of metals and other surfaces requiring a cleanly scoured surface have relied on tripoli in the United States for more than 150 years. Tripoli's Mohs hardness value of 7 ensures that abrasion of most surfaces can be accomplished using a finely ground quartz compound. The extremely fine-grained and well-sorted nature of the finished products and, indeed, of some of the naturally occurring outcrop materials makes tripoli a preferred abrasive. It is used in toothpaste and dental office polishing compounds, industrial cleansers, and metal and jewelry polishing compounds. It also has a secure place in the automotive industry, which uses it in an assortment of buffing and polishing compounds in lacquer finishes.

Particle shape is very important in the abrasives industry. Pulverized or extremely finely ground (micronized) tripoli and microcrystalline silica products, unlike ground silica produced from whole-grained silica sand, do not contain quartz grains with very sharp edges. The product milled from tripoli or microcrystalline silica consists of minute clusters of very small quartz crystals in which projecting crystals present a milder abrasive action than that possible using ground whole-grained silica. Pulverizing and micronizing followed by air classifying are the major steps in producing the various particle-size grades needed by the different markets. The coarser grades for the buffing and polishing compound markets are made by air-flotation size classification following pulverizing. The finely ground grades used mainly in the functional fillers and coatings markets are micronized in attrition mills that can produce material with a 2 μm diameter.

American Tripoli of Seneca, Missouri, markets a complete line of metal finishing compounds that grade from its aggressive cutting agent, Once Ground, through its Double Ground, Air Float, Premium R-45, and C-45 products to its finest buffing compounds, R-30 and C-30. These products are used to cut and polish progressively softer metals and metal finishes. The R-30 and C-30 grades are used to polish aluminum, chromium, and brass. These grades also serve as a buffing agent for mirrored picture frames, small ornaments, display metals, coins, and other highly reflective metal surfaces.

Although most of American Tripoli's production is sold into the abrasives industry, some of their products, notably the R-15 and C-15 grades, are consumed in the plastics and polymer segments in molded epoxy compounds, where they impart higher impact resistance and higher flexural strength.

Malvern Minerals of Hot Springs, Arkansas, markets its Novacite tripoli products into the abrasives markets, citing their superior purity and a lower abrasive coefficient as compared to other naturally occurring silicas (Figure 2). Harbison-Walker Refractories Company Inc. produces crude and finished material in Hot Springs County for use in the manufacture of refractory bricks and shapes (Dolley 2002). Unimin Specialty Minerals sells virtually none of its products into the abrasives industry.

Paint formulations for exterior and interior enamels and latexes benefit from the use of microcrystalline silica in several ways. As a functional filler and extender, microcrystalline silica aids in the durability, flowability, leveling, and tint retention of paints. Particularly in enamels, it makes the painting process easier and improves the sheen of the finished surface. Because of microcrystalline silica's chemical inertness in most environments, its use extends the life of the end product and prevents chalking, which can shorten the life of calcium carbonate-filled paints. Nonreactive microcrystalline silica improves resistance to salt spray, and its durability is reflected in its improved weatherability compared to other paints. The producers of microcrystalline silica for paint fillers and extenders also point to its low oil absorption properties. This characteristic allows it to be loaded into the paint with additional pigment without seriously affecting the viscosity. Low oil absorption also makes it easier to disperse microcrystalline silica than some other pigments used in paints. The hardness of microcrystalline silica compared to other fillers such as talc, kaolin, or calcium carbonate is a clear improvement over softer and more reactive mineral fillers. The hardness of microcrystalline silica is not always a benefit, however. Its presence can cause increased wear on the sprayers used in applying highway paints, marine paints, floor paints, and other applications where a hard, durable, painted surface is desirable.

Unimin Specialty Minerals Inc., of Elco, Illinois, markets a line of Imsil grades as functional fillers and extenders to the paint, plastics, rubber, adhesives, and sealant industries. Imsil fillers range from the relatively coarse A-75 grade, which has a median particle size of 12 μm , a TAPPI brightness value of 82.0, and a surface area of 1.3 m^2/g , to the A-8 product (Figure 3), which has a median particle size of 2.1 μm , a TAPPI brightness value of 86.4, and a surface area of 2.0 m^2/g . Malvern Minerals Company also sells its three Novacite products, 325, 1250, and L-207A, into the functional fillers markets, citing an average particle size for their best grade of 35 μm and a high Hegman fineness value of 67, which ensures smooth and complete dispersion in oil- and water-based paint systems.

Microcrystalline silica is an important added ingredient in plastics, rubber, sealants, and adhesives manufacturing processes. Microcrystalline silica is much less expensive than the organic resins that are used in plastics. In electrical cable coverings and other specific applications where insulating properties are critical, the dielectric properties of quartz make microcrystalline silica a desirable filler. Microcrystalline silica acts as a white base for plastics, rubber, and many sealants and adhesives. It is opaque, allowing the material to accept pigments more effectively and to provide a good level of color saturation. Also important is the strength benefit that comes from using microcrystalline silica in a plastic formulation, because it increases the rigidity of the finished plastic. In rubber applications, microcrystalline silica is added as a nonreinforcing filler. Using microcrystalline silica in the manufacture of rubber

printing rollers improves their wear resistance. Microcrystalline silica is widely used in grouts, sealants, and high-performance epoxy cements. Up to 60 % of some epoxy compounds can be composed of this material.

REGULATORY AND ENVIRONMENTAL CONSIDERATIONS

The question of the effect of crystalline silica on human health has been one of the most important issues in the industrial minerals industry in recent years. Silicosis is the disease usually associated with exposure to crystalline silica dust; it is a debilitating, incurable, and sometimes fatal lung disease. It is also a preventable disease (NIOSH 2002). The U.S. agencies that regulate workplace exposure to respirable crystalline silica are the Occupational Safety and Health Administration (OSHA) and the Mine Safety and Health Administration (MSHA). The OSHA permissible exposure limit (PEL) and MSHA exposure limit for respirable quartz and tripoli, based on an 8-hr time-weighted average, is the fraction 10 mg/m^3 divided by the sum of the percentage of quartz or tripoli in the sample plus 2. If the respirable dust has a high percentage of quartz or tripoli, this is close to an occupational exposure limit of 0.1 mg/m^3 .

Since 1974, the U.S. National Institute of Occupational Safety and Health (NIOSH) has recommended a more stringent exposure limit of 0.05 mg/m^3 as a time-weighted average for up to a 10-hr workday over a 40-hr workweek. NIOSH had stated that its recommended exposure limit (REL) will remain at 0.05 mg/m^3 until improved sampling and analytical methods are developed to better measure exposure to respirable silica (NIOSH 2002). NIOSH also recommends that companies find acceptable substitute materials for crystalline silica where feasible, use appropriate respiratory protection when source controls cannot reduce the exposure below the recommended exposure limit, and make medical examinations available to exposed workers. The American Conference of Governmental Industrial Hygienists (ACGIH) has adopted a threshold limit value of 0.05 mg/m^3 for respirable quartz.

The microcrystalline silica industry and its customer base are well aware of the health risks posed to their workers. Some production facilities of microcrystalline silica are among industry leaders in the effort to reduce and eliminate this hazard in their workplaces.

Indeed, the silicosis health effects of silica exposure have long been recognized as problems for workers in the mining industry. Georgius Agricola (1499–1555), in his pioneering mining volumes *De Re Metallica*, published the year after his death, described diseases experienced by miners and the means to prevent them. Paracelsus (1493–1541), in his book on occupational medicine, published 15 years after his death, included a section on the lung diseases that afflict miners (Goldsmith 1994). The advent of the industrial revolution brought power tools to the workplace to improve worker productivity. These tools increased dust exposures in occupations such as knife grinding, mining and tunneling, metallurgy, flint grinding, pottery making, and sandblasting. Workers in many of these jobs developed severe respiratory ailments, and Edgar Collins, working in the early years of the twentieth century, demonstrated that silicosis was the lung disease of many dusty trades, and that it was caused by the inhalation of “free” or crystalline silica (Collins 1919). Much of modern society’s knowledge of the problem of silicosis stems from Collins’ work (Goldsmith 1994).

Research in recent decades has focused on other diseases that may be caused by crystalline silica exposure. The International Agency for Research on Cancer (IARC) concluded in 1997 that “[t]here is *sufficient evidence* in humans for the carcinogenicity of inhaled crystalline silica in the form of quartz or cristobalite

Figure 3. SEM photograph showing the textural aspects of Unimin Specialty Minerals’ A-8 lsil product. This is the most finely ground product from the plant in Elco, Illinois.

from occupational sources,” but noted that “carcinogenicity in humans was not detected in all industrial circumstances studied” and that “[c]arcinogenicity may be dependent on inherent characteristics of the crystalline silica or on external factors affecting its biological activity or distribution of its polymorphs” (IARC 1997, pp. 210–211). IARC classified “crystalline silica inhaled in the form of quartz or cristobalite from occupational sources” as “carcinogenic to humans” (Group 1) (IARC 1997, p. 211).

The 1997 conclusion by IARC followed a conclusion 10 years earlier that there is “*limited evidence* for the carcinogenicity of crystalline silica in humans” (IARC 1987b), which resulted in the classification in 1987 of crystalline silica in IARC’s Group 2A, which it terms “probably carcinogenic to humans” (IARC 1987a).

Also in 1997, the American Thoracic Society (ATS) found that “the available data support the conclusion that silicosis produces increased risk for bronchogenic carcinoma” (ATS 1997). However, the ATS noted that there was less information available concerning lung cancer risks among silicotics who had never smoked and for silica-exposed workers who did not have silicosis (ATS 1997).

The U.S. National Toxicology Program (NTP) considers crystalline silica (respirable size) to be a substance “known to be a human carcinogen” (NTP 2000).

NIOSH has also noted case reports published about autoimmune diseases or autoimmune-related diseases found in crystalline silica-exposed workers or in silicotics, as well as epidemiologic studies reporting statistically significant excesses in cases or deaths from autoimmune diseases or immunologic disorders (such as scleroderma, systemic lupus erythematosus, rheumatoid arthritis, and sarcoidosis), chronic renal disease, and subclinical renal changes in persons exposed to crystalline silica. Other adverse health effects have been reported as well (NIOSH 2002).

OSHA is engaged in a rulemaking proceeding to adopt a substance-specific rule covering crystalline silica exposure. OSHA submitted a conceptual version of the rule to the Small Business Administration in 2003 pursuant to the Small Business Regulatory Enforcement Fairness Act (OSHA 2003). MSHA has stated that it is considering several options to reduce miners’ exposure to crystalline silica (MSHA 2003).

In 2000, the U.S. Environmental Protection Agency (EPA) added silica (crystalline) to the list of substances that it proposed to study for addition to EPA's Integrated Risk Information System (IRIS) (EPA 2000). In 2004, EPA announced that it had removed silica (crystalline) from the list of substances to be added to IRIS because of limited EPA resources and lower overall priority (EPA 2004).

OUTLOOK AND FUTURE TRENDS

In the coming decade, all significant microcrystalline silica and tripoli production in the United States is expected to continue. Minor production in Spain and Russia has been noted, but nothing is known regarding any future activities. Exports from the United States to other industrialized countries will persist and perhaps increase slightly, especially with respect to the finest ground, highest value products that fill important market niches in the high-durability, high-strength, extended-life paint markets; the high-strength plastics markets; and other special applications functional fillers markets for rubber, sealants, and adhesives. Mining techniques will probably not change significantly in the near future because they are what might be considered commonly employed techniques for a variety of commodities. The introduction of open-pit mining in 1983 and the closing of the underground mine in the Illinois District represented a significant change in one district. It seems likely that the most significant changes in this industry over the next 10 years will be found in new developments in the processing of these commodities and perhaps the development of new specialized markets. Improved sophisticated processing techniques now used may allow production of even brighter and finer-sized products. Processes such as wet grinding, chemical leaching, and high-intensity magnetic separation could be used if the high end of the market justified these additional costs.

The future trend of tripoli and microcrystalline silica use is downward, in large part because of the stringent warnings against exposure in the workplace to crystalline silica dust in excess of the NIOSH-recommended exposure limit of 0.05 mg/m^3 . NIOSH is likely to reduce the REL as soon as reliable sampling and analytical methods are developed to better measure exposure levels below the REL. Other, less objectionable, finely ground abrasives and functional fillers will probably continue to substitute for tripoli and microcrystalline silica where possible. Competing minerals such as kaolin, talc, calcium carbonate, nepheline syenite, and mica are ever-present competitive challenges in the filler and extender markets.

Vermiculite

James R. Hindman

INTRODUCTION

Vermiculite is the mineralogical name generally applied to the group of minerals commonly formed by the alteration of biotite and iron-bearing phlogopite. Vermiculite retains the micaceous form and sheet silicate atomic structure of the parent mica, but differs in that a change in the net charge of the silicate sheets results in the tightly held potassium atoms in the mica structure being replaced in whole, or in part, by other cations and their associated hydrate shells. In microscopic particles, vermiculite is differentiated from other clay minerals by a high silicon:aluminum (Si:Al) ratio of approximately 3:1, and a higher layer charge that results in a generally higher cation-exchange capacity. Commercial vermiculite, the vermiculite that is mined, beneficiated, and discussed in this chapter, is an important industrial mineral. Vermiculite possesses a number of important properties that include high aspect ratio particles in a range of sizes from less than 50 μm to more than 1 cm, a high ion-exchange capacity, directional intumescence, and an active crystal surface with catalytic properties.

Within the internal structure of vermiculite lie water molecules that, when rapidly heated to high temperature, transform into steam, causing the vermiculite particles to increase in volume. This process of thermal exfoliation produces a lightweight product that finds use in various construction products and in agricultural, horticultural, and other industrial applications. In exfoliated form, it has the low density and biological inertness of expanded perlite, while maintaining a chemically active surface. Most of the vermiculite mined worldwide is ultimately consumed in the thermally exfoliated form.

In addition, the cation-exchange potential of vermiculite and its layer-silicate structure are properties that can be used as the basis for numerous products, including intumescent coatings and gaskets and inorganic films, and for the treatment of nuclear and other toxic waste. When chemically and physically modified, it possesses some properties common to organoclays and synthetic compounds. In high-purity concentrates and manufactured products, these properties can be altered and optimized in applications to produce superior performance.

GEOLOGY Mineralogy

Thomas H. Webb first described vermiculite in 1824. He believed vermiculite to be a variety of talc and described its diagnostic property of thermal exfoliation thusly (Webb 1824, p. 55): "If subjected to

the flame of a blowpipe, or that of a common lamp, it expands and shoots out into a variety of fanciful forms, resembling most generally small *worms* having the *vermicular motion exact*." It is difficult to give a short and precise definition of vermiculite, but in the following discussion, vermiculite will refer to that industrial mineral commodity that has been formed by the alteration of biotite and iron-bearing phlogopite by groundwater, and macroscopic particles of which are deformed by exfoliation when heated rapidly to temperatures well above 374°C.

The vermiculite Webb studied was from a locality near Worcester, Massachusetts, but Brush (1866) later pointed out that vermiculite had been known for some time in Japan as a children's novelty. Because the techniques for mineral analysis used then were somewhat primitive compared to those routinely available today, and because the structure and crystal chemistry of the micas and related minerals were not widely understood, the early literature generated at least 20 "new" minerals that were nothing more than variations in the color and chemistry displayed by vermiculite. Trade names such as Dugarlite, Mandolite, Stro ng-Lite, and Zonolite are sometimes used to denote commercial vermiculite, thermally exfoliated vermiculite, and their related products.

Vermiculite particles resemble mica and vary in color from colorless through tan and green to black, depending on the chemical composition. Most physical and optical properties are close to those of biotite, with perfect basal cleavage, hardness between 1.5 and 2.5 on the Mohs scale, and specific gravity between 2.2 and 2.8. Fine-sized particles will feel talcose, especially when wet. For commercial vermiculite, however, the diagnostic test is thermal exfoliation.

Vermiculite can display a wide range of compositions, depending on the composition of the original mica and the change of chemistry during weathering and ion exchange. Table 1 gives chemical data for some commercial vermiculites and an average analysis based on a composite of 65 published analyses. Numerous analyses for vermiculite exist in the literature, and the analyses of vermiculites from commercial deposits fall within the range of values reflected in average analysis in the table. Many analyses separate the adsorbed water (H_2O^-) from crystalline water and water as hydroxyl (H_2O^+). The basis of separation of adsorbed water is generally considered to be 100°C, although molecules of water associated with cations within the vermiculite interlayer begin to be lost at 75°C and sometimes lower. Therefore, measured water content and loss on ignition are combined in the table as $\text{H}_2\text{O}^{\text{[total]}}$.

Table 1. Selected chemical analyses of vermiculite*

Analysis	A-65	V-1	V-2	V-3	V-4	V-5	V-6	V-7	V-8	V-9

The average chemical component values calculated from 65 vermiculite analyses suggest a typical formula of

where the components in the first set of parentheses represent the ion-exchangeable layer, the components in the second set of parentheses compose the cations of the octahedral layer, and the components within the brackets constitute the tetrahedral layer. The actual amounts of Na⁺, K⁺, Mg⁺⁺, and/or Ca⁺⁺ in the interlayer (represented here as IX1 through IX4 for the mole contents of Na⁺, K⁺, Mg⁺⁺, and/or Ca⁺⁺, respectively) vary significantly in nature and can be easily manipulated in the laboratory by ion exchange. The total number of exchangeable cations in the interlayer is limited by the overall charge of the silicate sheets. The chemical composition of commercial vermiculite varies significantly from one mine to another, and significant variations in the chemistry of the ion-exchangeable layer can occur within a particular deposit. Generally speaking, calcium vermiculite and magnesium vermiculite are the predominate components of commercial vermiculite; potassium vermiculite also is a common component.

Many authors have investigated the crystal structure of vermiculite. The basic structure of the mineral is identical to talc and the micas: a 2:1 silicate sheet comprising two flat layers of silica and aluminum tetrahedra (the tetrahedral layers) that are joined together in a layer composed of apical oxygen atoms, and magnesium, iron, and hydroxyl molecules (the octahedral layer). Between the 2:1 sheets lies the ion-exchangeable layer. This layer differs in

thickness depending on the interlayer cation present and the arrangement of water molecules associated with it.

Interlayer water is an essential component of vermiculite. When a particle of vermiculite is rapidly heated, the interlayer water transforms into steam. The pressure of the steam forces the silicate layers apart from one another, deforming the particle from the normally flat plate into an elongated, concertina-like particle, which forms the basis of most commercial applications of this mineral. The increase in volume caused by the thermal exfoliation is normally in the range of 10 to 20 times, with typical exfoliated densities of 90 to 110 kg/m³.

The basal d-spacing of vermiculite obtained by x-ray diffraction (XRD) varies according to the composition of the ion-exchangeable layer. Mathieson and Walker (1954) detailed the arrangement of hydrated magnesium ions in 14 angstrom (Å) vermiculite. Other common basal d-spacings occur at 12 Å (i.e., barium, sodium, and strontium vermiculites) and 10 Å (i.e., potassium and ammonium vermiculites). Brindley and Brown (1980) and de la Calle and Suquet (1988) offer more detailed discussions of the crystal structures of vermiculite. These three common basal reflections represent cations with 6- and 8-fold coordinated water molecules (~14 Å), cations with water molecules in 3-fold planar coordination (~12 Å), and those structures where the exchangeable cations and water molecules lie in the hexagonal or ditrigonal cavities in the planar silicate sheet surface (10 Å). Stated another way, the 14-Å vermiculite structure has two layers of water molecules between the silicate sheets, the 12-Å vermiculite structure has a single layer of water molecules between the silicate sheets, and the

10-Å vermiculite has a single layer of water molecules embedded in the surface of the silicate sheets.

The hydrated interlayer cations are easily subject to ion exchange. Typical ion-exchange values for vermiculite concentrates are 50 to 150 meq per 100 g. If properly exfoliated, thermally exfoliated vermiculite will also have a high ion-exchange capacity that is diminished only 5% to 10% from the untreated material. The rate of ion exchange is relatively slow with potassium vermiculite, owing to the lack of interlayer separation.

Two common misconceptions are found in much of the literature dealing with the crystal structure of vermiculite as revealed by powder XRD. Gruner (1934) used the term *hydrobiotite* to indicate regularly alternating layers of biotite and vermiculite. This mixed structure would produce a 12-Å basal reflection, which is common in commercial vermiculites. The 12-Å reflection, however, is relatively broad and does not shift after ion exchange as one would expect. For example, consider a vermiculite containing the normal sharp 14-Å reflection and the broad 12-Å reflection. After ion exchange with a sodium ion solution, the 14-Å will disappear but no 11-Å reflection is created as would be expected as a result of the alteration of 10 Å biotite and 12 Å Na-vermiculite. The broad 12-Å reflection may be caused by a combination of calcium, magnesium, or sodium ions in a single layer, and associated water molecules define the thickness of that layer.

The other common assumption in XRD studies is the assignment of the 10-Å reflection to the presence of biotite. Potassium vermiculite is a common component in commercial vermiculites and is indistinguishable from biotite using routine XRD techniques. Not all researchers are aware that potassium vermiculite does contain interlayer water. Water molecules fill structural vacancies caused by the leaching of excess potassium during vermiculitization of biotite. Many commercially desirable vermiculites will contain the 10-Å reflection in their XRD spectra, and this reflection may represent the hydrated potassium vermiculite as opposed to biotite. This misinterpretation of the XRD data may be a source of confusion in studies on the formation and ion-exchange characteristics of vermiculite.

Origin

A number of studies indicate that vermiculite can be formed from a number of silicate minerals. Because the vermiculite that is mined and processed for industrial applications must produce salable concentrates of relatively large particles, however, the parent mineral is invariably an iron-bearing phlogopite or biotite. The well-known exception to this is the unique deposit at Llano, Texas, where iron-free phlogopite occurs in magne site, and the vermiculite thus formed upon weathering is a pure magnesium vermiculite variety widely used in crystallographic and geochemical studies.

The alteration of biotite into vermiculite takes place at near-surface conditions so that all known deposits are supergene in origin. Studies by Roy and Romo (1957) indicate that vermiculite will not form as a primary mineral and that it is not stable under hydrothermal conditions. The alteration of biotite into vermiculite appears to take place in two steps that can be illustrated using a hypothetical biotite and ferric iron in solution. First, the ferrous iron is oxidized within the octahedral layer:

This process, unless accompanied by the loss of interlayer potassium, results in an imbalance of charge and an increased separation between the 2:1 silicate layers. The repeat distance of the crystal structure increases from the typical 10-Å value to approximately 11 Å.

The second step in vermiculite formation begins when the silicate layers of the mica are separated sufficiently to allow for ion exchange. The excess potassium content of the interlayer is taken into the groundwater according to

And finally the content of the remaining exchangeable-ion interlayer is altered to reflect the ionic content of the groundwater within the deposit, as in the case of magnesium vermiculite:

The transformation of biotite into vermiculite requires an increase in particle volume of 10% to 40%. Although not immediately obvious, this volume-increase requirement places restrictions on the size and placement of a vermiculite deposit. To form vermiculite, the alteration products of biotite must literally lift all of the overlying rock body. Unless the lithostatic pressure can be exceeded by the forces caused by the oxidation of iron within biotite and the subsequent ion exchange, no vermiculite formation can take place. This pressure has not been measured directly, although some related data are available (i.e., Norrish and Rausell-Colom 1963; Viani, Roth, and Low 1985). Empirical geological evidence suggests that the pressure will coincide with the 25- to 30-m maximum ore depth found in many deposits.

Distribution of Major Deposits

Vermiculite is currently being mined in at least nine countries. Figures 1 and 2 show those current sources, and known potential sources of commercial vermiculite in the United States and worldwide.

The first production of commercial vermiculite began in the United States in 1915 with the unsuccessful marketing of tung ash, the name given to vermiculite mined near Hecla, Colorado. Actually, vermiculite was inadvertently mined in the 1800s as a major accessory mineral in the corundum deposit in the Jenks mine in North Carolina (Cooke 1874).

The vermiculite mine started by the Zonolite Company at Libby, Montana, in 1921 was the first successful venture in the vermiculite industry. Until recently, the Libby deposit was the oldest producing vermiculite mine and had been developed and enlarged for almost 70 years. This property was closed in 1990, and that closure has had a major impact on the vermiculite industry, especially in the United States.

Vermiculite has been mined in other locations in the United States. Excellent summaries of statewide vermiculite deposits and mining have been prepared for Colorado (Bush 1951), North Carolina (Murdoch and Hunter 1946), Texas (Claybaugh and Barnes 1959), and Wyoming (Hagner 1944). Other discussions of vermiculite deposits in the United States include Bush and Sweeney (1968) on the Appalachian region and Bush (1976) for the entire country. With regard to individual deposits, doctoral dissertations have dealt with Libby (Boettcher 1966a) and with Enoree, South Carolina (Libby 1975).

Current production in the United States is restricted to mines in South Carolina and Virginia. Several mining operations are located in northwestern South Carolina. The two major producers—W.R. Grace & Company at Enoree and Carolina Vermiculite at Woodruff—account for most of the production in that state. A smaller operation, Palmetto Vermiculite, is in the same area and serves a smaller regional market.

The other major domestic vermiculite mine is near Louisa, Virginia, and is operated by Virginia Vermiculite. Virginia Vermiculite

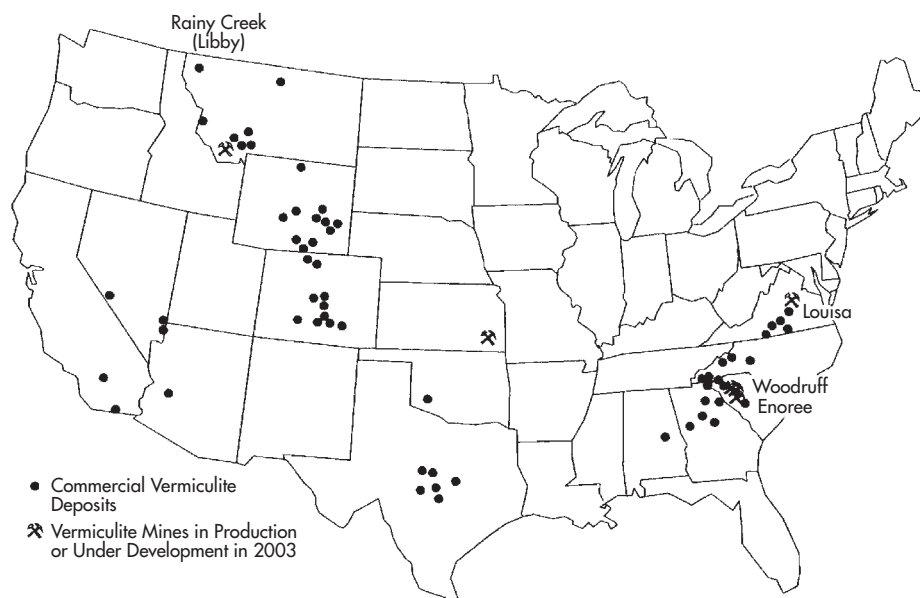

Figure 1. Major U.S. vermiculite mines and deposits

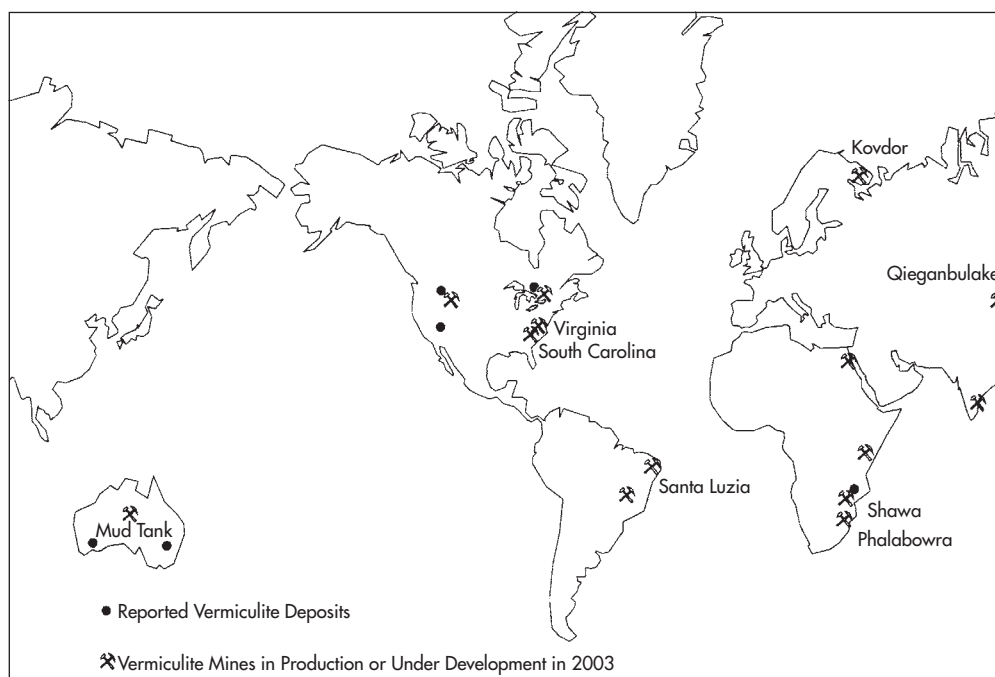

Figure 2. Major worldwide vermiculite mines and deposits

purchased Carolina Vermiculite in 1990, and the combined production capacity of the two operations is on par with the production capacity of the Grace plant at Enoree. Figure 1 shows the locations of known, major vermiculite deposits and current mining operations. Table 2 presents U.S. vermiculite production and trade data since 1980.

Vermiculite is also mined in Kansas, although the product is not considered commercial vermiculite because of its microscopic

particle size. Micro-Lite LLC operates a mine in Woodson County from which an altered lamproite with an appreciable phlogopite and vermiculite content provides a material useful in animal feed supplements.

The closure of the Libby operation left the western United States with no major domestic source of vermiculite. Several known deposits have been considered for development or reopening as mining operations. One small deposit at Elk Gulch near

Dillon, Montana, has sporadically produced small tonnages of concentrate under different operators between 1990 and 2000. Deposits near Hamilton and Pony, Montana, near Encampment, Wyoming, and at Mica Peak in Clark County, Nevada, are periodically evaluated for their potential as new sources of vermiculite.

Within the last few years, two potential new sources of vermiculite in Ontario, Canada, have been under development. Regis Resources of Toronto recently began to ship vermiculite concentrates from a small mining operation near Buckhorn, in Carleton Place Township. The ore is found in altered red schist and gneiss associated with other Precambrian metamorphic rock types. The vermiculite ore is found in separate small zones over a relatively large area. The vermiculite from this deposit tends to have a low iron content, and the exfoliated product has a good bag yield and is often almost white.

Another vermiculite deposit in Ontario is located in Butler Township near North Bay. Some initial mining has been performed, and a small wet processing plant has been constructed at the site.

With the closure of the Libby mine and mill, the Republic of South Africa has become the leader in worldwide vermiculite pro-

duction, with production of 224,258 t in 2002 and 207,345 t in 2003. The Palabora Mining Company operates the mining operation at Phalaborwa, and copper is the primary product. The Phalaborwa deposit is also known as Loolekop and has been described in a number of papers such as Gevers (1949).

Other current vermiculite-producing countries include Australia, Brazil, China, Egypt, India, Japan, Kenya, Russia, and Zimbabwe. Recent data (Potter 2004) suggest that the top three producing countries are South Africa (46%), the United States (21%), and China (10%). Moeller (2004) suggests that worldwide vermiculite production in 2003 was approximately 425,400 t. Figure 2 shows the worldwide location of known, major vermiculite deposits and current mining operations. Table 3 summarizes worldwide vermiculite production and trade data since 1980.

TECHNOLOGY Exploration

The exploration for vermiculite deposits is straightforward because they are the products of surface and near-surface weathering. Because one criterion of commercial vermiculite is large grain size,

† Production for United States in 1997 assumed here to be average of reported 1996 and 1998 values.

exploration is directed toward geologic structures that might contain large amounts of large biotite crystals. The most common structures are ultramafic intrusives such as coarse-grained pyroxenites and metamorphic bodies containing biotite schists and gneisses.

Good vermiculite ore is friable and easily broken with a standard prospector's hammer. A small propane torch is useful for field identification purposes. The basic criterion for vermiculite ore is that the individual particles can be seen with the unaided eye and that they will exfoliate when subjected to high heat. An average content of from 20% to 35% vermiculite in the ore will produce mill feed that is easily processed with current technologies. Higher-grade feeds may allow for a smaller mill design and operating costs, whereas lower-grade ores can be processed if the quality of the concentrates obtained is acceptable. The grade, particle-size distribution, and general quality of vermiculite within an ore body may vary widely, and the larger mining operations blend ore to provide a consistent feed to the beneficiation plant. The amount of vermiculite in particle sizes less than 0.25 mm or that will pass through a 65-mesh Tyler screen are not generally included in the valuation of an ore deposit because there is no significant market for this material and it is intentionally rejected during beneficiation.

Bush (1976) classifies vermiculite into three classes. The Type 1 deposits are formed within large ultramafic intrusive masses such as pyroxenite plutons, are cut by syenite or alkalic granite, and are cut by carbonatitic rocks and pegmatites. The deposits at Libby, Montana, and Phalaborwa, Republic of South Africa, are Type 1. The rock masses in Type 1 deposits are often zoned. Type 2 deposits are formed in association with smaller ultramafic intrusive masses such as dunite and peridotite and unzoned pyroxenite. The deposits in North Carolina are of this type. The Type 3 deposits are formed from metamorphic rocks such as biotite schists and amphibole schists. The deposits at Enoree, South Carolina, and Elk Gulch, Montana, are Type 3, as are most of the deposits in Colorado, Nevada, Texas, and Wyoming.

Other classification schemes for vermiculite have been proposed. The classification of Borovikov (1962) comprises four groups: group 1—deposits in ultrabasic and alkaline rock complexes; group 2—deposits in altered carbonate rock complexes; group 3—vermiculite occurrences in reaction zones of pegmatites, talc, corundum, asbestos, and other deposits, and also in metasomatic veins in serpentines; and group 4—deposits and occurrences of vermiculite in micaceous gneisses and other metamorphic rocks. The major deposits at Kovdor and Buldym in Russia are group 1 deposits.

L'vova (1974) gives a detailed discussion of vermiculite deposits worldwide. Varley (1952) describes most of the known vermiculite deposits and discusses the technical and economic aspects of commercial vermiculite, giving information that is still applicable half a century later.

Mining and Beneficiation

The mining and milling of vermiculite depend on a number of considerations not associated with other mineral commodities. Unlike most other ores, the value of a vermiculite ore depends on the distribution and efficient recovery of relatively large particles. A vermiculite ore will normally contain vermiculite, partially altered mica, unaltered mica, and associated gangue minerals.

In the very early years of the industry, the ore bodies were selectively mined (high graded) and the sized ore was the final product of beneficiation. As these areas of relatively pure vermiculite were depleted, and the demand for coarse-sized products

increased, mills were designed to beneficiate the ore. Although high-grade areas within a particular deposit may still be encountered, modern milling techniques require feeds more consistent with the overall character of the ore body.

Vermiculite is normally mined using open-pit methods. There have been reported instances of underground mining, such as at the Quaintance deposit in Jackson County, Colorado (Goldstein 1946), but these operations were on a small scale that would not be economically feasible in today's industry.

Modern vermiculite mines are invariably developed by excavating the deposit with conventional equipment, including graders, shovels, loaders, and trucks. Drilling and blasting may be necessary in areas where dikes, sills, and other hard bodies of rock occur within the ore body. When the mill is at the mine site, large off-highway trucks transfer the ore to the mill. Some operations such as at Enoree, South Carolina, and Louisa, Virginia, use smaller capacity trucks operating on highways and improved roads to bring ore from deposits that are some distance from the mill site. In either case, the ore is taken to an area near the mill where the larger pieces of waste rock are removed and the ore is blended and stockpiled. Blending can be accomplished by a number of methods, ranging from spreading the ore with a bulldozer to using a water monitor to wash the ore from the stockpile into the mill.

Beneficiation techniques used with vermiculite take advantage of one or more properties of the mineral. These properties include shape, density, chemistry, and resistance to comminution. Some of these properties may be applicable to both wet and dry processes, but most mills do not beneficiate with both wet and dry processes.

Figure 3 is a generalized flow diagram for a dry beneficiation mill. Typically, ore processed in a dry mill requires some drying before sizing. Air classification is the normal beneficiation process in a dry mill and separation is effected by winnowing and other techniques such as air tabling. Electrostatic and high-intensity magnetic techniques may be effective in some instances, as are morphology separations using roll and slot screening.

Separating the feed into narrow size ranges that correspond to the finished concentrates assists the selectivity of air classification. Comminution primarily reduces the size of gangue minerals for removal during recycling through the air separators. In many ores, major gangue minerals are friable or possess distinct cleavage. In these cases, the vermiculite particles may pass through impact or roll crushers relatively unaffected, and the bulk of the gangue particles are reduced to sizes that are easily removed by air separators or by screening during the recycle process.

Wet beneficiation of vermiculite generally falls into two categories: froth flotation for fine particle sizes below 1 mm and beneficiation techniques based on morphology for larger particles. Because many vermiculite ores contain major amounts of dense gangue minerals, processing steps using heavy-media separation, jigs, spirals, and shaking tables can be effectively used. Simple hydroclassification may also be effective in treating fine-sized ores, and flotation circuits can be improved and possibly replaced by hydrocyclones, hydraulic classifiers, and teeter chambers in some instances.

Figure 4 shows a hypothetical wet processing circuit. Processing of fine-sized material is straightforward, and most common flotation cells and tables are effective. Processing larger particle sizes is more difficult, and most processes take advantage of the tendency of the vermiculite plates to adhere to or travel along a smooth surface. Moving water films on plates and other flat surfaces can sometimes be used with excellent selectivity. Vaplon, Erickson, and Young (1978) claim wet-roll screening to be effective in processing large particles of vermiculite. This is the separation device shown in Figure 4 as an example of beneficiation by shape.

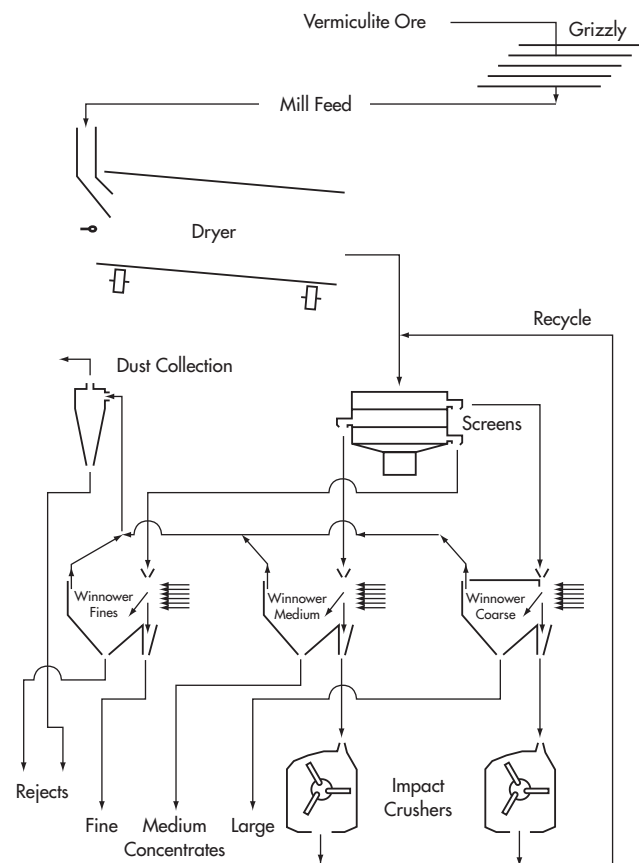

Figure 3. Processing circuit for the dry beneficiation of vermiculite ore

Vermiculite concentrates are marketed with specified particle-size distributions. The beneficiation circuitry in dry-processing plants may produce the finished product sizes without further treatment. In wet-processing plants, drying the combined mill concentrates produces the mill product. In this case, the dried concentrate is processed into the sized products in an additional screening facility.

Processing

Most vermiculite is consumed in the thermally exfoliated form. Usually, unexfoliated vermiculite concentrate, weighing 640 to 1,120 kg/m³, is shipped in 100-t hopper railcars from the mills to exfoliating plants throughout the United States and Canada. In recent years, there has been a growing trend to distribute vermiculite in smaller ton truck shipments of 10 to 20 t from centrally located distribution centers. This is especially true for vermiculite imported from China and South Africa.

In the United States, most exfoliation takes place in vertical furnaces in which the sized vermiculite concentrate falls through a hot zone produced by gas or oil burners. Exfoliation begins during the brief residence time in this zone, at 900°C or hotter, and continues during accumulation in a hopper at the base of the furnace. The temperature and residence time in the hot zone determine density and appearance of the exfoliated vermiculite and the oxidative or reductive nature of the burner flame.

Another type of furnace used to exfoliate vermiculite is a rotary drum furnace. This type of furnace is commonly used out-

Figure 4. Processing circuit for the wet beneficiation of vermiculite ore

side North America. The sizing and design of a rotary furnace used to exfoliate vermiculite are not necessarily appropriate for the thermal expansion of perlite, and one should not assume that any furnace will process vermiculite and perlite equally well.

Other furnace types have been used to exfoliate vermiculite, and the Torbed design seems to be effective with some concentrates that require higher temperatures or longer residence times. The Torbed furnace treats the vermiculite as a rotating fluid bed. Reports of good results in processing vermiculite in Torbed furnaces have been made.

After the vermiculite has been exfoliated, an air separator removes the nonexfoliating gangue material. Purified product is then packaged in 0.1-m³ (4-ft³) paper bags for shipment. In larger plants, the exfoliated vermiculite may be ground into powder or mixed with other materials to produce horticultural blends and industrial compositions. Some exfoliation plants may also expand perlite. Table 4 lists vermiculite exfoliation plants known to be in operation during 2003.

Specifications and Testing

Vermiculite concentrates are invariably screened into various size ranges before shipment from the mill and further processing. In the United States, screening results in finished products with a mean particle diameter either one-half or double that of coarser and finer grades, respectively. Nominal top and bottom screen sizes used for various grades are 6.30 to 3.35 mm (3 and 6 mesh Tyler) for grade

number 1; 3.35 to 1.7 mm (6 and 10 mesh Tyler) for grade number 2; 1.7 to 0.85 mm (10 and 20 mesh Tyler) for grade number 3, etc. Imported concentrates are similarly sized, except on a metric scale. Approximate top and bottom sizes for these concentrates are 8.0 to 4.0 mm (2.5 mesh to 5 mesh Tyler) for grade large; 4.0 to 2.0 mm (5 to 9 mesh Tyler) for grade medium; 2.0 to 1.0 mm (9 to 16 mesh Tyler) for grade fine, etc. The actual particle-size distributions in vermiculite concentrates from a particular processing plant may vary because of changes in the character of the ore being processed or to match market demand. There is normally no issue involved with substitution of a metric-sized product for a similarly sized American product. For a vermiculite concentrate of equal grade and quality, metric sizing will produce a slightly larger average particle size, thus a slightly better bag yield.

Ores and concentrates are normally analyzed for both grade and particle-size distributions. The dried sample is screened into various size fractions using sieves and a mechanical shaking device. In the United States, this is typically a Ro-Tap and a stack of U.S. or Tyler screens. Each screen fraction is weighed and then exfoliated in a furnace at 800° to 950°C. After cooling, the samples are again weighed and water flotation separates the exfoliated vermiculite from the gangue material. The remaining gangue is dried and weighed. The vermiculite concentrate is then calculated by simple difference or, if

the vermiculite has been well characterized, using a formula that accounts for excess moisture or overdrying of the sample.

Because of the cost of mining and beneficiation, and the cost of transportation of the finished concentrate, mining and producing high-grade ores and products is preferred. Although lower grades can be tolerated in some cases, ore feed grades are normally in the range of 20% to 35% vermiculite. Very high grade ores are sometimes encountered that contain more than 80% vermiculite.

An average grade of 90% is common for finished concentrates, and some concentrates occasionally approach 99% vermiculite. The concentrates also have specifications for the relative performance of the material during thermal exfoliation. This can be measured from samples of concentrate by laboratory exfoliation in specially designed furnaces that simulate the performance of commercial exfoliating plants.

Quality control of the exfoliated vermiculite is routinely maintained by either weighing the packaged product as 0.1-m³ or 4-ft³ bags (bag weight) or by counting the number of bags produced from known amounts of concentrate (bag yield).

USES

Vermiculite finds use in a number of diverse applications, of which a representative few are discussed here. Vermiculite is used in products and applications in three primary forms: untreated concentrate, thermally exfoliated, and the ground products of chemical or thermal exfoliation. Conventional uses for thermally exfoliated vermiculite include horticultural products such as growth media, construction products such as lightweight aggregates, high-temperature insulation, and as a primary component in cementitious coatings.

Cementitious mixtures of thermally exfoliated vermiculite and binding agents, such as gypsum plaster, have been important products. Monokote, a product marketed by W.R. Grace & Company, is applied to structural steel members in commercial buildings (Bragg and Rothfelder 1973) and has consumed major amounts of domestic vermiculite production.

Vermiculite is used in building boards of various types. Fine-sized, untreated vermiculite concentrates are included in the preparation of fire-resistant plaster board (Green and Sundberg 1971). Thermally exfoliated vermiculite can be mixed with appropriate binders and pressed into boards and other shapes (Tomandl 2002). Pressed vermiculite board could be used as a replacement for gypsum plaster board in many applications, but its primary use is for high-performance fire stops and protective enclosures.

Because of its high absorbency and chemical inertness, thermally exfoliated vermiculite has been used in industrial applications for many years. One product consists of long fabric tubes or socks filled with exfoliated vermiculite. These tubes are marketed as *pigs* by the New Pig Corporation and are distributed in the United States and exported worldwide. This product is used primarily to contain oil and similar liquids.

Ground thermally exfoliated vermiculite is produced by two domestic vermiculite companies and is also imported from the Republic of South Africa. The major use of this material is in friction materials such as a replacement for asbestos in brake linings. Ground vermiculite is also slurried with clay minerals for refractory mold release and other coatings. Ground exfoliated vermiculite is used in various refractory board products.

Dispersions of ground chemically exfoliated vermiculite are produced and marketed for various coating and film-forming applications. George F. Walker developed the first technology of vermiculite dispersions at the Commonwealth Scientific and Industrial Research Organization (CSIRO) in Australia in the 1960s. The

preparation and use of vermiculite dispersions have been the topic of a series of patents by a number of individuals, beginning with Walker (1967). Imperial Chemical Industries PLC (ICI) has done further research on preparing and using vermiculite dispersions, and product applications have been developed for increasing the thermal stability of glass cloth, flexible films, and plastic fillers. Armstrong World Industries and Hercules Incorporated have also done similar research.

W.R. Grace & Company is currently the major supplier of vermiculite dispersions in the United States, having acquired many of the patented applications and technologies of ICI. Grace markets vermiculite dispersions as Microlite, and Firespray International Ltd. manufactures and markets vermiculite dispersions as Aqualite in England.

The temperature at which vermiculite begins to undergo thermal exfoliation varies by composition of the ion-exchangeable layer. Langer and Marlor (1981) took advantage of this phenomenon to prepare intumescent gasketing material using low-temperature exfoliating NH_4^+ vermiculite. This gasketing material is used extensively in wraparound mats to cushion catalytic converter assemblies in automotive applications. Minnesota Mining and Manufacturing and the Unifrax Corporation Intumescent currently manufacture seals.

Untreated vermiculite concentrates are also used in some intumescent gasket applications and to reduce slag buildup on boiler tubes, primarily in coal-fired electric utilities (Engstrom and Bain 1983). Dearborn Chemical Company markets vermiculite used in this application as Firemate.

Although the immediate market effects of new domestic and imported sources of vermiculite are not clear, the entry of new companies into the industry should produce new opportunities for growth. Vermiculite dispersions constitute only one new area. One should expect that vermiculite, in all of its forms, will continue to find application in detoxification of water and soil, nuclear waste containment and removal, and industrial spill containment and cleanup.

ECONOMIC FACTORS

Many of the end uses of vermiculite are associated with construction and various industrial uses. Until the early 1990s, the consumption of vermiculite tracked the national economy to some extent, and the amount of vermiculite produced and consumed in the United States generally increased over a period of close to 70 years. The closure of the Libby operation in 1990 marked the end of this era of continued growth.

It is difficult to do a detailed analysis of the vermiculite market using production and trade data because most vermiculite companies treat all business data as proprietary. The U.S. Geological Survey (USGS), however, has been collecting and summarizing production and trade since 1996; before 1996 the U.S. Bureau of Mines (USBM) collected the data. It is generally acknowledged that the data from USGS and USBM are the most accurate data available for the U.S. vermiculite industry. However excellent the data may be for determining trends and qualitative evaluations, one should use caution when attempting quantitative economic analyses for several reasons. First, the USGS and USBM data have been obtained primarily from a voluntary annual survey. Response to the survey is not legally required, nor is accuracy enforceable. Second, the value-added aspect of vermiculite products may go well beyond the listed valuations of the thermally exfoliated vermiculite, such as would be the case with vermiculite dispersions.

Other sources of data and general industry reviews are available, including the annual reviews published by USGS (<http://minerals.usgs.gov/minerals/pubs/commodity/vermiculite>) and *Mining*

Engineering, the most recent of which have already been mentioned. The periodic reviews of the worldwide vermiculite industry published by Roskill Information Services (<http://www.roskill.co.uk>) are highly recommended. The Vermiculite Association (<http://www.vermiculite.org>) is an international industry organization now headquartered in London. Founded in 1948, the membership is drawn from vermiculite mining companies, exfoliation plant operators, and other industry professionals involved in the manufacture of vermiculite-based products.

The market price of vermiculite concentrates varies with particle size, with the larger-sized products commanding higher prices relative to the more abundant finer sizes. The Libby closure has eliminated the only major source of coarse-sized concentrates in the United States, and since the end of 1991 essentially all +2-mm vermiculite consumed in North America has been imported from South Africa and China, with minor amounts coming from Australia, Brazil, and Zimbabwe.

Typical market prices for domestic vermiculite concentrates currently range from \$60 to \$170/t, depending on size and grade. Prices for imported vermiculite concentrates range from \$12.7 to \$240/t, free on board (f.o.b.) Gulf Coast Port (Moeller 2004).

Vermiculite became an important industrial mineral because of uses developed for its thermally exfoliated products. Although there are significant current and developing markets for nonexfoliated and ion-exchanged vermiculite concentrates, at least 90% of commercial vermiculite is marketed after thermal exfoliation. It is not surprising, therefore, that the basic unit of vermiculite trade after leaving the mine and mill is bags, the major description of quality is bag yield, and the profitability of a processing plant is keyed to the cost per bag. The cost per bag of exfoliated vermiculite is a combination of the price of vermiculite concentrate at the mine, plus the total cost of transportation to the exfoliation plant, plus the cost of exfoliation, packaging, and distribution. The value is calculated based on the number of 0.1-m³ or 4-ft³ bags of exfoliated vermiculite obtained from the total amount of concentrate processed, including the gangue minerals (also known as grit or rock). It is not uncommon for the cost of transportation to approach 50% of the cost per bag.

The bag yield (i. e., quality) of vermiculite concentrates depends on several variables, including the grade of the concentrate and the size distribution of the vermiculite particles. Although the actual bag yield depends on the type of furnace used and the operating conditions, the amount of thermal exfoliation of a vermiculite concentrate can be measured by various laboratory techniques. The average value for all exfoliated vermiculite produced in the United States is approximately \$390/t, according to recent USGS estimates.

HEALTH ISSUES

There are no health issues reported to exist as a result of normal handling and general exposure to vermiculite. Hessel and Sluis-Cremer (1989), Addison (1995), and Chatfield (2001) discuss the relative safety of vermiculite. Although not attributed to vermiculite, one widely reported situation is linked to the asbestiform amphibole minerals found in the Rainy Creek vermiculite ore body near Libby, Montana. The health issues associated with some former workers at the former Zonolite mine and mill are complex and beyond the scope of this chapter.

INDUSTRY TRENDS

Perhaps a good indication of current trends in the vermiculite industry is the development of new products and applications for vermiculite. In 2004, there were 23 pending U.S. patent applications dealing directly with vermiculite. Of those 23 patent applications, roughly

half deal with products or uses for ~ 1 mm product sizes including vermiculite dispersions. The use of vermiculite in sprayable cementitious fireproofing products in the United States decreased in the 1990s because of W.R. Grace's introduction of MK-6 (containing shredded polystyrene) to replace MK-5 (containing exfoliated vermiculite). In recent years, other products with the same general composition and performance as the widely used MK-5 became readily available from other sources. For many years, Palabora America Ltd. (a subsidiary of the Palabora Mining Company, formerly known as American Vermiculite Company) has been the sole source of South African concentrates in the United States, and Mandoval (a former subsidiary of Palabora) has distributed the material in Europe. Mandoval produced fireproofing and related products at a plant in Texas until 1998. Currently, cementitious fireproofing products containing vermiculite are manufactured by Isolotek International as CAFCO Fire Protection products and by Southwest Vermiculite Co., Inc., as Type 5GP.

New products for waste treatment and disposal may create significant new markets for vermiculite. Major tests at an electric power plant in Ohio began in 1992 to evaluate the effectiveness of thermally exfoliated vermiculite coated with magnesium compounds to treat flue gases. Initial test work indicated significant reductions of sulfur and nitrogen gas emissions (Nelson 1988), and success of this technology on a large scale could foreshadow a significant increase in demand for the mineral. More recently, Lovell, Turchi, and Brokerick (2004) used ion-exchanged vermiculite to remove mercury from flue gas.

Vermiculite in both untreated and thermally exfoliated forms has catalytic properties. It is expected that continued research will find uses for vermiculite of both forms, and vermiculite modified for use in organic and inorganic chemical treatment, nuclear storage, water purification, and toxic waste treatment.

Wollastonite

Sara M. Robinson, Ken Santini, and Jay Moroney

INTRODUCTION

Wollastonite is named after W. H. Wollaston (1766–1828), an English chemist and mineralogist. It is a calcium metasilicate with the chemical formula CaSiO_3 . Wollastonite is the only naturally occurring, nonmetallic, white mineral that is acicular (needlelike) in crystal habit. This crystal habit and the mineral's chemistry are the main reasons for wollastonite's rise in commercial use, which began in the 1970s and has continued to the present. As a nontoxic partial substitute for short-fiber asbestos, wollastonite became sought after in many polymer systems where mechanical strength and heat stability are needed. The end uses range from friction brake materials to fire-resistant asbestos board to ceramic tile to industrial coatings. Exterior automotive parts and under-the-hood applications have benefited from the use of high-aspect-ratio grades of wollastonite.

Until recently, the United States was the leading producer of wollastonite. In the last few years, however, China and India have emerged as major producers. In 2005, China and India were ranked the number one and two largest producers in the world, respectively. In Europe, another producer and major supplier, Partek, exited the business, and in 2005 sold only small amounts to a select customer base.

GEOLOGY

Mineralogy, and Physical and Chemical Properties

Wollastonite, a member of the pyroxenoid mineral group, has the theoretical composition of 48.3% CaO and 51.7% SiO_2 . Iron, manganese, magnesium, or strontium may substitute for some of the calcium. Associated minerals include andradite, grossular, diopside, calcite, quartz, tremolite, epidote, apatite, sphene, and plagioclase feldspar. Wollastonite is primarily chemically inert; however, it can be decomposed in hydrochloric acid as well as other strong inorganic acids. Organic acids, such as acetic acid, have little or no effect. In commercial applications, wollastonite has demonstrated effective resistance to the actions of organic solvents, including oxygenated versions.

Some wollastonite will fluoresce under shortwave or long-wave ultraviolet light, or both, with colors ranging from pink–orange to yellow–orange and, more rarely, bluish green. Wollastonite may show phosphorescence.

Because of its unique cleavage properties, wollastonite breaks down during crushing and grinding into lathlike or needle-shaped

particles of varying acicularity. This particle morphology imparts high strength, making it of considerable importance in many markets. The acicularity of particles is defined by their length-to-width ratio. Wollastonite is marketed as either low-aspect-ratio (generally 5:1 or less) and high-aspect-ratio (generally 12:1 and higher). Diameters, on the other hand, can range from a low of 2.5 μm to a high of more than 40 μm . Generally, the low-aspect-ratio grades are used as functional fillers where chemistry carries an equal value to morphology. Examples of end uses are found in architectural and industrial coatings, ceramic bodies and glazes, and foundry applications. The high-aspect-ratio grades contribute functionality, with the morphology playing a more important role than the chemistry. Examples include engineering resin compounds (such as nylon and polypropylene), phenolic molding compounds (such as friction brake materials), and rubber matrices (such as gaskets). In these applications, wollastonite has served to fill the niche originally held by asbestos.

The dry brightness and whiteness of wollastonite are also important in determining its suitability for certain filler and ceramic applications. When pure, the mineral is brilliantly white, but impurities may color it cream or gray. Brightness is determined by measuring the reflectance of finely ground powder against a standard that is assigned a brightness of 100. Magnesium oxide and barium sulfate are the two standards used. *GE brightness*, a term used in North America, refers to brightness measured with a General Electric reflectometer. Commercial wollastonite products usually have a GE brightness ranging from 85 to 95. The Hunter method is also used to measure the brightness of wollastonite.

Loss on ignition (LOI), another important property in determining applications for wollastonite, is the amount of volatile matter driven off when the mineral is heated to 1,000°C. Commercial wollastonite products have an LOI ranging from 0.5% to 2.0%.

Wollastonite's naturally high pH of 9.9 (10% water slurry) is of major importance to its use in the coatings industry. The alkaline pH has been thoroughly documented as a chief contributor to wollastonite's corrosion-inhibiting performance in heavy-duty industrial coatings. Table 1 lists some of the selected properties of wollastonite.

Origin and Mode of Occurrence

Wollastonite is formed by both metamorphic and magmatic processes that usually involve carbonate and intrusive igneous rocks.

Table 1. Selected wollastonite properties

Crystal system	Triclinic
Crystal habit	Bladed masses; acicular
Cleavage	2 perfect at 84° and 1 good
Color	White, sometimes cream, gray, or very pale green
Streak	White
Luster	Vitreous to pearly
Mohs hardness	4.5–5.0
Specific gravity	2.87–3.09
Melting point	1,540°C
Transition point to pseudo-wollastonite	1,200°C
Thermal coefficient of expansion (mm/mm/°C)	6.5×10^{-6}
LOI	1,000°C
pH	10–11

Two types of deposits are known—skarn deposits (thermal metamorphic and metasomatic) and carbonatites (magmatic).

Wollastonite-rich skarn deposits are formed by the thermal metamorphism of siliceous limestone during regional deformation or as a result of local intrusive igneous activity. The mineral can also form through the metasomatism of limestone by siliceous hydrothermal solutions along contacts with igneous intrusions or along fractures and faults.

Wollastonite is formed by the following reaction:

At low temperatures, quartz and calcite will form a stable assemblage, as in certain types of marble. If the temperature rises to approximately 400° to 450°C, however, the reaction begins and proceeds to the right until the supply of calcite or quartz is exhausted, at a pressure of about 1×10^5 Pa. The carbon dioxide produced causes pressure to increase unless this gas escapes, and as the pressure rises, the temperature required for the reaction to proceed increases, possibly to as high as 950°C.

The mineral composition of each wollastonite deposit is dependent on geologic conditions, so the assemblage of associated gangue minerals differs from one deposit to another and even within a single deposit. Nevertheless, three basic assemblages are generally associated with wollastonite: wollastonite–garnet (grossular–andradite)–diopside (e.g., Lewis, New York); wollastonite–calcite–graphite (e.g., Harrisville, New York); and wollastonite–diopside–quartz (e.g., Lac St. Jean, Quebec). Each assemblage reflects the original composition of the host rock and the nature of subsequent metamorphic and intrusive igneous events.

A number of workers have studied the occurrence and origin of wollastonite deposits in the Adirondack Mountains, Essex County, New York. These deposits are held by NYCO Minerals, Inc., a subsidiary of Fording Canadian Coal Trust. The ore bodies are typified by a simple equilibrium assemblage of wollastonite–grossular–diopside (de Rudder 1962). Accessory minerals are apatite and sphene. Wollastonite is intercalated with bands and lenses of grossular–andradite and diopside–hedenbergite. The formation of wollastonite depended on the initial composition of the Precambrian Grenville carbonate rocks and was independent of silica metasomatism. Thermal metamorphism produced wollastonite in siliceous limestones, diopside in siliceous dolomites, and garnet in argillaceous limestones. Minor alumina metasomatism from adjacent argillaceous sedimentary rocks caused the development of thick grossularitic skarns bordering the ore bodies.

The wollastonite in Essex County is associated with mafic metasedimentary rocks (amphibolites and pyroxene gneisses) having mineral assemblages characteristic of both hornblende–granulite and pyroxene–granulite subfacies of regional metamorphism. de Rudder (1962) concludes that the gneissic structure of these metasedimentary rocks, their granulitic texture, the lack of recognizable metamorphic halos, and the high-grade mineral assemblages indicate that relatively high temperatures and pressures prevailed for long periods of time. The mafic metasedimentary rocks enclose a wollastonite–grossular–diopside assemblage that is considered typical of either the hornblende–hornfels or the pyroxene–hornfels facies of contact metamorphism. As a result, de Rudder proposes that the conditions of metamorphism can best be termed *thermal-load metamorphism*, and defines this term in the context of thermal metamorphism caused by the proximity of magma at great depths and very high uniform pressure.

The environment of metamorphism at NYCO's deposits must be inferred from field relations, mineral assemblages, thermodynamics, and experimental data. Based on these criteria, de Rudder (1962) believes that the range of temperature and pressure most consistent with known data is 750° to 950°C and 6 to 12×10^8 Pa. This would correspond to a burial depth of approximately 30 ± 10 km.

O'Hara (1976) disputes de Rudder's statement that the origin of NYCO's wollastonite was a contact metamorphic event triggered by the intrusion of anorthosite into granulite facies rocks at a depth of 30 km and a temperature of 750° to 950°C. Instead, O'Hara suggests that uplift occurred after regional metamorphism and before the anorthosite intrusion. Thus, the anorthosite intruded the metasediments in a low-pressure environment (e.g., about 2×10^8 Pa and 650°C). The heat from the intrusion caused thermal metamorphism of metasedimentary rocks and the crystallization of wollastonite.

Other authors (Grammatikopoulos, Clark, and Vasily 2003) attribute the formation of high-grade wollastonite skarn deposits (e.g., NYCO) to *infiltration metasomatism*. In this model, wollastonite development resulted from the interaction between infiltrating fluids, calcitic marble (possibly intercalated with dolomitic marble), and clastic, quartz-rich domains. The fluids were controlled by fractures and porosity of the original beds.

Wollastonite is also found in carbonatites, where it crystallized from carbonatite magma. Carbonatite deposits generally are found as near-surface intrusions associated with nepheline syenite or nephelinite in complexes of elliptical or circular outline. Wollastonite deposits in carbonatites are of lower grade than skarn deposits but are potentially economically valuable. It is improbable that a carbonatite would be mined for wollastonite alone, but the mineral might be obtained as a by-product.

WORLD WOLLASTONITE DEPOSITS AND ACTIVITIES

United States

Two companies in the state of New York produced wollastonite commercially in 2005. The NYCO operation is in northeastern New York (Essex County), near Lake Champlain, within the boundaries of Adirondack Park. R.T. Vanderbilt Company has an operation in northwestern New York (Lewis County), near the St. Lawrence River.

NYCO is the largest of the two domestic producers with 2004 sales of 82 kt (includes the operation in Mexico described in the relevant section in this chapter), with a value of \$34.8 million. From 1943 to 1982, NYCO mined wollastonite from the Fox Knoll deposit, initially by open-pit and later by underground methods. The deposit is approximately 4 km southwest of NYCO's processing plants at Willsboro. After the Fox Knoll deposit was shut down, the Lewis deposit, which is about 23 km southwest of the plants, became

Table 2. Selected Canadian wollastonite deposits

Name	Location	Resource
Deloro	Marmora, Ontario	2 Mt at 40% wollastonite
Mount Grove	Olden Township, Ontario	2.7 Mt containing 32% wollastonite, 63% calcite, and 5% diopside
Seeley's Bay	Kingston, Ontario	9 Mt, grading 41% wollastonite 3 Mt, grading 30% wollastonite
Lac St. Jean	Quebec	5 Mt, proven at 37% wollastonite
Montreal–Gatineau area	Quebec	Unknown; numerous deposits
Wormy Lake	Sechelt Peninsula, British Columbia	50 Mt

Table 3. Major current and past wollastonite producers in Mexico

Name	Location	Output, Finished Product, t	Markets	Current Status
General de Minerales SA (Lamosa Group)	Guadalupe, Zacatecas State	20,000 (1993)	Domestic ceramics primarily	Plant shut down in 1995; current status unknown
Minerales y Maquiles del Norte, SA	Santa Catarina, Zacatecas State	9,000	Primarily ceramics and metallurgical	Produces low-aspect-ratio grades with 85% of production for domestic consumption
Minera NYCO SA de CV	Northwest of Hermosillo, Sonora (Pilares deposit)	240,000 t nameplate capacity	Global; powder products (e.g., ceramics)	Started operations in 1997, but significantly curtailed planned production; estimated annual production of <30,000 t
Compania Minera de Cerralvo	Near Pichucalco, Chiapas State	1,000	Domestic paint industry	Wollastonite was by-product of copper operation; current status unknown

the feedstock source. Wollastonite comprises up to 60% of the Lewis ore, with 30% garnet and 10% diopside accounting for the balance. The deposit averages 49% wollastonite. Additional reserves are available at NYCO's Oak Hill deposit, averaging 45% wollastonite. A third deposit, Deerhead, grades 25% wollastonite. According to NYCO, the three deposits total 6 Mt of reserves.

All of NYCO's deposits were formed by contact metamorphism and metasomatism of Precambrian siliceous carbonates by an anorthosite intrusion. NYCO's processing plants at Willsboro produce a full product line ranging from a milled (low-aspect-ratio or powder) grade of $-45\ \mu\text{m}$ (-325 mesh) to surface-modified, $-10\ \mu\text{m}$ (-1250 mesh), high-aspect-ratio (15:1 to 20:1) products. Magnetic separation removes accessory garnet and diopside from the wollastonite. Jet mills are used for producing high-aspect-ratio products.

The R.T. Vanderbilt deposit is near Harrisville, and started production in 1977. In 2005, both underground and open-pit operations were active. The deposit was formed by contact metamorphism and metasomatism of Precambrian siliceous carbonates by a syenite intrusion. It differs from NYCO's deposits in that garnet is absent. The ore contains up to 90% wollastonite, with associated blue calcite, graphite, prehnite, magnetite, and diopside (Gerdes and Valley 1994). The ore body is differentiated, with large pods of wollastonite being separate from gangue zones. This allows selective mining of the ore zones. Wollastonite ore is crushed at the mine site and then trucked approximately 19 km to a plant near Balmat. Both low-aspect-ratio and high-aspect-ratio grades are produced. Some of the products are surface treated. Estimated production is 40 ktpy.

Other deposits, mostly in the western United States, have been explored with past attempts at starting operations. In the late 1990s, the American Wollastonite Mining Company (currently known as Previa Resources Ltd.) was evaluating and seeking investment capital for a deposit near Tonopah, Nevada. Stated reserves were more than 1 Mt at 60% wollastonite, with an aspect ratio of 16:1. Although a 10-kt pilot plant was under construction at one time, this venture had ceased as of 2005.

Canada

In Quebec, Orleans Resources reported in the 1990s that it had the potential to be a major producer. Because of certain technical and marketing problems, however, the operation ceased production by 2000, and the plant has been completely dismantled. As of 2005, only one deposit was actively being evaluated, the Seeley's Bay property owned by the Canadian Wollastonite Company. The company was seeking a joint-venture partner.

The deposits that have had the most exploration and development are concentrated in Quebec, Ontario, and British Columbia. The geology is primarily anorthosite associated with marble and calc-silicate rocks (see Table 2).

In most, if not all, of these deposits, flotation and magnetic separation would be required to process the mineral to achieve yields approaching 90% wollastonite. Most of the deposits are reported to have at least an 8:1 aspect ratio, and some aspect ratios are >20:1. Ram Petroleums Ltd. originally evaluated the Mount Grove deposit in 1990. With a stated aspect ratio range of 17:1 to 24:1, planned production called for 30 ktpy of wollastonite and 54 ktpy of calcium carbonate. The economic viability is unknown, and the project is believed to have been terminated.

Mexico

The established and known producers of wollastonite are concentrated in the states of Zacatecas and Sonora. Production in 2003 was estimated at 52 kt (Virta 2004). Other states where wollastonite has been produced include Chiapas, Durango, Morelos, and Tabasco. Table 3 shows details of the major current and past producers in Mexico.

Minera NYCO mines wollastonite from the Pilares deposit. The deposit is situated in a north-dipping sequence of Paleozoic calcitic marbles and quartzites in close proximity to granitic rocks of Cretaceous age. The San Hector deposit is near the Pilares deposit. Reserves grading more than 50% wollastonite and containing >100 Mt are represented by the two deposits combined. As of 2005, the San Hector deposit was dormant. The Minera NYCO

Table 4. Wollastonite producers in China, 2001

Name	Location (Province)	Capacity, tpy	Resource	Number of Mines
Lishu Wollastonite Mining Industry Co.	Mostly in Jilin and Liaoning	80,000	~ 20 Mt	10
Nanchuan Minerals Group	Guangdong and Jilin	30,000 and 10,000, respectively	Unknown	2
Sanyi Mining Development Co.	Jilin	60,000	Unknown	4
Jilin Wollastonite Development Co., Ltd.	Jilin	24,000 (mill capacity) 50,000 (mine capacity)	1.5 Mt	1
Xinyu South Wollastonite Industry Co., Ltd.	Jiangxi	50,000 (lump) 20,000 (milled)	Unknown	Unknown
Anhui Pioneer Mining Co., Ltd.	Anhui	20,000 (lump) 6,000 (milled)	Unknown	2
Daye Wollastonite Mine	Hubei	30,000 (lump)	Unknown	Unknown
Dayu Mineral Materials Co., Ltd.	Liaoning	20,000	Unknown	Unknown
Changxing Wollastonite Mine Co., Ltd.	Zhejiang	25,000 (lump and high-aspect-ratio)	Unknown	Unknown

facility utilizes both flotation and magnetic separation to remove calcite, quartz, and diopside from the wollastonite.

China

Approximately 50 deposits have been discovered in 19 provinces. Of these, 30 deposits have been extensively explored (Lu 1998). The deposits are concentrated in the provinces of Jilin, Yunnan, Jiangxi, Qinghai, and Liaoning. Resources are estimated at 130 Mt. China holds the largest number of deposits and mines and is considered to be the world's largest wollastonite producer (Virta 2004). Output from viable operations is believed to be about 300 ktpy, with domestic consumption approximately 100 ktpy (Moore 2003; Hawley 2004). Chinese wollastonite dominates in powder grades for ceramic and metallurgical applications and recently, high-quality, high-aspect-ratio grades have emerged.

Table 4 lists the major producers in China in 2001 (Kendall 2001; Virta 2004).

In 2004, it was reported that China produced from 60 small operations (Hawley 2004). The industry, however, has consolidated, resulting in nine companies controlling ore processing and production in 2005. The Jilin Wollastonite Development Co., Ltd. signed an agreement in 2004 with S&B Industrial Minerals S.A., pending Chinese government approval. In this agreement, S&B would have 51% control and would manage the operation (Virta 2004).

India

In 1969 the Belkappahar wollastonite deposit was discovered near the village of Khila in the Jodhpur Division of Rajasthan State. The deposit consists of three zones of wollastonite interbedded with pyroxenites and garnet-bearing gneisses that have replaced limestone. The ore contains about 96% wollastonite, associated with minor calcite, garnet, diopside, and quartz. Proven reserves are estimated to be approximately 50 Mt, and probable reserves are about 200 Mt. Wolkem India Ltd. operates two open-pit mines, one at Belka Pahar, the other at Kheratarla. The plants are at Sirrohi and Udaipur, and produce milled, high-aspect-ratio, and surface-modified grades. Wolkem serves various markets, including ceramics, metallurgical, coatings, and plastics. Production for 2003 is reported to range from 160 kt (Mahajan 2003) to 176 kt (Virta 2004). India ranks as the world's second leading producer of wollastonite.

Finland

Partek Industrial Minerals produces wollastonite as a flotation by-product with calcium carbonate. The operation is in southern Finland near Laappeenranta. At one time, the company was rated the

world's fourth largest producer of wollastonite. In 2004, however, production was only 27.5 kt. The wollastonite occurs in the central portion of an elliptical body of Archean limestone. Within the wollastonite deposit are stringers of calcite, dolomite, quartz, diopside, and lepidite. Reserves are estimated at 3 to 4 Mt at an average grade of 20% wollastonite, although the grade reaches 60% in certain areas. The company also controls another wollastonite deposit at Savitapale that is estimated to contain 20 Mt grading 25% to 35% wollastonite.

Other Countries

Other small producers of wollastonite include Estudios y Proyectos Mineros Ltda. in Chile; Kalemden in Turkey; Morocco Minerals Co. in Morocco; Atiriver Mining Ltd. in Kenya; and Namaqua Wollastonite Pty Ltd. in South Africa.

In addition to the countries listed, lesser amounts of production are reported for Pakistan and North Korea (Bolger 1998). Undeveloped wollastonite deposits have been documented in Serbia, the Czech Republic, Poland, the Commonwealth of Independent States, Lithuania, Sweden, Spain, France, Italy, Greece, Switzerland, Namibia, Cuba, New Zealand, Australia, and Japan (Bauer, Copeland, and Santini 1994).

TECHNOLOGY

Exploration and Evaluation of Deposits

Exploration for commercial wollastonite deposits begins with defining the target parameters, which include the desired location, mineralogy, and minimum tonnage. A hypothetical example might be Ontario, Canada, with 5 Mt averaging +50% wollastonite with no calcite. The next step is to develop an exploration plan, which may include researching known deposits, mining districts, and other areas with a geological environment suitable for wollastonite formation. Favorable geological features may include igneous intrusions, such as anorthosites and syenites within a Precambrian metamorphic terrane containing calc-silicate rocks, such as those found in New York, Canada, and Finland. Jurassic and Cretaceous granites within a Paleozoic metamorphic terrane containing calc-silicate rocks, such as in the western United States and Mexico, are another example.

Once exploration targets have been established, an initial reconnaissance geologic examination of the selected areas is conducted. Geologists use various exploration techniques, including field checking for host lithologies based on existing geologic maps; geologic mapping of host lithologies using aerial photos; stream-sediment sampling (e.g., for associated garnet and diopside); grab or channel sampling or both; and mineralogical, physical, and

chemical testing of field samples. Geophysical techniques have seldom been used during regional reconnaissance, because wollastonite-rich rocks exhibit no pronounced gravimetric, electrical, or magnetic properties.

In some areas, such as NYCO's Fox Knoll, Lewis, Oak Hill, and Deerhead deposits, wollastonite-rich rock does not usually crop out, partially because of its relatively low resistance to weathering in humid climates. This can impede the early stages of exploration. In such areas there may be geomorphological features that can be used in tracing wollastonite horizons. Wollastonite that is very coarse grained or contaminated with quartz (or both) can remain exposed after long periods of chemical weathering. Typically, the mineral is more resistant to weathering in arid climates, such as in certain parts of Mexico and the western United States.

After prospects have been identified, a more detailed geologic examination is conducted. This includes geologic mapping, core drilling, and trenching. Wollastonite samples generated during this phase of exploration are subjected to x-ray diffraction for mineralogical analysis and x-ray fluorescence for chemical analysis. In addition, LOI, brightness, and aspect ratio are determined. Petrographic examination of thin sections from selected samples can be useful as well.

If the exploration phase yields favorable results, it is then necessary to extract a bulk sample of representative material from the deposit for additional testing to determine what marketable products can be produced. The bulk sample is subjected to the same tests as the drill core samples. Based on analytical results, the bulk sample may be beneficiated by dry or wet laboratory-scale methods to upgrade the material to standard commercial specifications by removing gangue minerals. Laboratory-scale test work may include combinations of the following steps depending on whether a dry or wet process is required: hand sorting, crushing, screening, pebble or ball mill grinding, flotation, high-intensity magnetic separation, thickening, filtration, drying, and pebble and jet mill grinding. Products resulting from beneficiation tests are subjected to the same analyses as the core samples. In addition, products are tested for surface area, bulk density, oil absorption, and particle size distribution. Scanning electron microscope (SEM) photographs of each product are also taken.

Mining

Wollastonite deposits are mined by open-pit and underground methods. Drilling and blasting are necessary to fragment the wollastonite. At the wollastonite deposits in New York's Essex County (held by NYCO), for example, both mining methods have been employed. Open-pit mining at the Fox Knoll deposit began in 1951. Increasing overburden combined with the dip of the wollastonite horizon resulted in higher stripping ratios, requiring mining operations to move underground in 1959. The deposit was mined by underground methods until it was closed in 1982. Production shifted to the Lewis deposit, which is mined by open-pit methods with bench heights of 10 m. Wollastonite is crushed at the mine site and transported to the plants at Willsboro, New York, for further processing.

Processing

Because the mineralogy of wollastonite largely determines whether it can produce high-purity concentrate, that mineralogy is the key issue in evaluating a deposit. Ideally, an ore-processing system should be capable of recovering a concentrate of at least 97%—if not 99%—wollastonite. Important mineralogical factors include the type of gangue minerals present, the grain size, and the extent to which grains of constituent minerals are intergrown.

Deposits of wollastonite commonly contain garnet and diopside, which are nonwhite and must be removed. Both of these minerals are weakly magnetic, and therefore can be removed from the wollastonite using high-intensity magnetic separators. Wollastonite is often associated with large amounts of calcium carbonate, which must be removed by flotation.

The general flowsheets in Figures 1 and 2 display the dry and wet methods employed to process wollastonite. In New York, NYCO uses the dry method; in Mexico, the company uses the wet method.

Other minor components are present in such small amounts, typically 0.5% and less, that they do not contribute to any wollastonite performance issues and do not need to be removed. MgO, MnO, TiO₂, and Al₂O₃ are examples of these components.

If a deposit is to supply all of the wollastonite markets, it must be able to yield high-aspect-ratio as well as milled (low-aspect-ratio or powder) product grades. Equally important is the particle size at which high-aspect-ratio grades can be produced. For example, it is possible to produce a 14:1 aspect-ratio grade with a diameter of 2.3 µm and another grade with the same aspect ratio that has a diameter of 9.0 µm. In this example, both will differ in average length of particles. To ensure optimum performance of high-aspect-ratio grades, controlling the top size and the amount of fines is also part of the processing technology.

Processing improvements integral to new product development focus on the following target markets:

- High-aspect-ratio, fine-particle-size grades used as reinforcements to compete against milled glass fiber, synthetic fibers, and whiskers
- Fine-particle-size, high-aspect-ratio grades to compete against other mineral reinforcements, such as talcs and clays, in thermoplastic compounds
- Incorporation of new coupling agents to expand the usefulness of wollastonite into emerging markets, such as wood composites

Specifications and Typical Reported Properties

Wollastonite specifications and typical reported properties follow:

- Milled grades: Particle size, including top and median diameter, are measured either by optical measuring devices or by sedimentation methods. Wet and dry screen retentions are commonly reported. Other specifications can include color (whiteness), brightness, oil absorption, LOI, loose and tapped bulk density, and particle size distribution.
- High-aspect-ratio grades: In addition to measurable particle size properties, loose and tapped bulk density are determined. Other properties can be screen analysis, surface area, and oil absorption. In one application (fire-resistant cement boards), sedimentation value is frequently requested as a specification.
- Chemically modified wollastonite: In addition to the specifications and properties listed in the first two bullets, the type of chemical and amount of residual active ingredient can be specified. Percentage of moisture is often noted as well.

Wollastonite By-products and Coproducts

An often critical aspect in the development of an industrial mineral deposit is the potential for selling by-products or coproducts. This is somewhat true of wollastonite, but is probably not as important as for other minerals.

In at least one operation, the Partek operation in Lappeenranta, Finland, wollastonite itself is the coproduct. The wollastonite occurs in a calcium carbonate deposit, which is the principal material

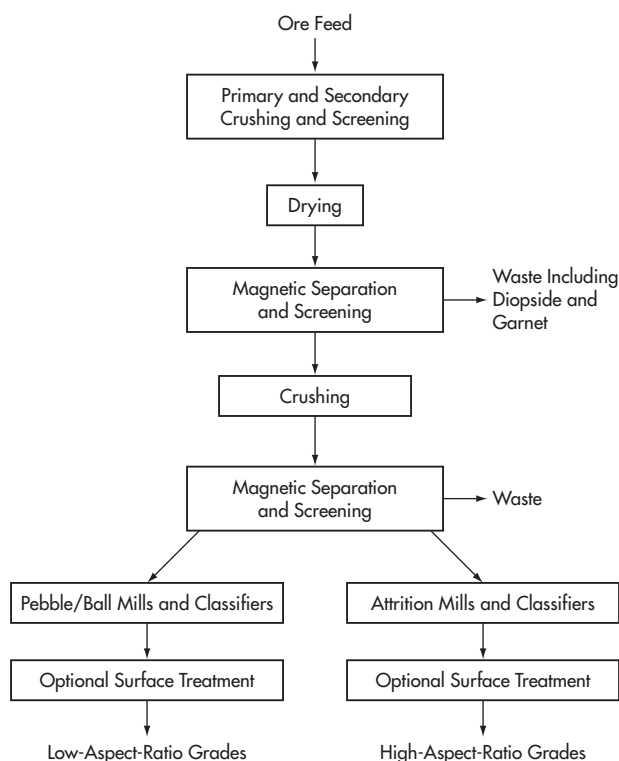

Figure 1. Wollastonite processing (dry)

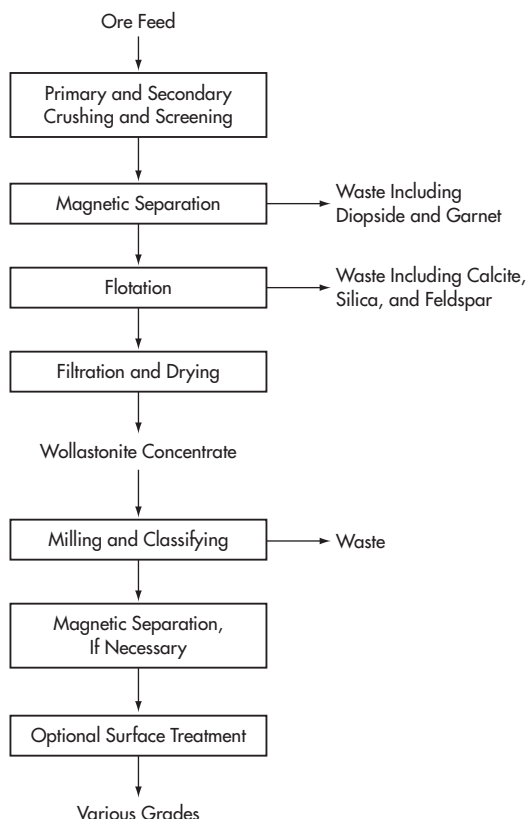

Figure 2. Wollastonite processing (wet)

coproduced. In this case, wollastonite would have to be mined and wasted if it were not recovered as a coproduct. Partek has successfully marketed and sold this high-quality form of wollastonite.

In another example, NYCO has successfully removed the garnet and diopside by-products at its operation in Willsboro, New York. These by-products are created by using high-intensity magnetic separation to remove the garnet and diopside from the wollastonite. The garnet is a substitute for silica sand in abrasive blasting and multilayer water-filtration systems.

In other operations around the world, the generation of by-products is less important. In some locations, however, wollastonite is found associated with calcium carbonate, which is removed using flotation. Once recovered, it is a source of lime for agricultural uses.

Synthetics

Synthetic calcium metasilicates have been produced commercially for many years in various parts of the world, including the United States, Denmark, Germany, Italy, and Brazil. Most of the synthetics are hydrous, and in contrast to naturally occurring calcium metasilicate, they have high absorptivity and lack the characteristic acicular shape.

The synthetic calcium metasilicates made in Denmark are produced from silica sand and chalk under the trademarked name of Synopal. Basically the process is slurring the chalk and silica sand with small amounts of dolomite, which acts as a flux. The slurry is heated to about 1,560°C in a kiln, forming a viscous paste that is then water cooled. When solidified, the material is crushed and screened, then reheated in a second kiln at 1,250°C, which facilitates crystallization. The finished product is subangular, white, and opaque, and consists of about 50% wollastonite and 50% gehlenite ($\text{Ca}_2\text{Al}_2\text{SiO}_7$) and akermanite ($\text{MgCa}_2\text{Si}_2\text{O}_7$). The Synopal wollastonite has been used in road surfacing, mosaic tiles, flooring, and roof tiles.

In Italy, a synthetic product has been produced in a method similar to the Danish process. Additional uses that have been mentioned include road material, abrasives, and ceramics. In Brazil, a synthetic calcium metasilicate had been produced for the welding rod flux, ceramics, and refractories markets. Recent reports, though, suggest that the company that produced this material is no longer providing the synthetic form.

In the United States, both hydrous and anhydrous calcium metasilicates have been manufactured by PPG Industries (Silene grade), and by Manville Products Corporation (Micro-cel). Many grades are reported to have been made of both types, and the typical manufacturing process is autoclaving lime, silica sand, and dolomite slurries at high pressures and temperatures.

In 2003, a U.S. patent was granted that disclosed synthetic calcium metasilicates and methods for producing them (Withiam, Conley, and Yannul 2003). The calcium metasilicates were described as having low aspect ratios (1:1 to 2.5:1) and oil absorptions from 20 mL/100 g to about 220 mL/100 g. In this patent, the end uses for the synthetic wollastonite are described as being a veterinary pharmaceutical preparation, a formed food product, a formed agricultural product, and a formed home care product.

Other uses for synthetic wollastonite have been those where the natural form has been used. The deciding factor is proximity of natural wollastonite, especially if the quality is high. Because of the necessity for purity of chemistry, the ceramics industry and the refractories industry have had to rely on the synthetic version in the past, although this seems to have declined in recent years. Synthetic calcium metasilicate is believed to be used in some flat glass manufacturing. A companion product, synthetic diopside, is made as a

source of magnesium. Other uses for the synthetic form have been as a flow aid in powdered materials, in foam manufacture, and in mineral wool.

ECONOMIC FACTORS

Demand and Consumption

According to Virta (2003), the major domestic supplier of wollastonite, NYCO, indicated that sales from its combined operations in Mexico and the United States were 75 kt in 2003. This is 11% less than reported in 2002. Reasons cited were global oversupply and offshore competition from suppliers in China and India. End-use sectors reporting declines in wollastonite consumption from the same study were ceramics (using calcium carbonate as a low-cost and local substitute) and metallurgical uses (lower steel production and using either lower-cost minerals or lower-cost imported wollastonite). Sales did increase to 82 kt in 2004.

Hawley (2004) reported the distribution of U.S. consumption of wollastonite for 2003 to be plastics (37%); ceramics (28%); paint (10%); metallurgical (10%); friction products (9%); and miscellaneous (6%). This latter category includes fire-resistant cement board (a type of wallboard), adhesives, sealants, and caulks. New markets are developing in cement and concrete compositions, and in selected rubber-based polymer sealants.

Demand for wollastonite is steady, with single-digit growth expected through 2010. Some sectors could experience more aggressive growth into double-digit figures, but the average of all industries is likely to be in the single digits. Competitive mineral products have influenced some of the consumption of wollastonite, especially in the engineered plastics market. The introduction of very fine talcs and nanoclays and other nanoparticle-size minerals into the plastics market has impacted the use of wollastonite. This has been noticed especially in the production of nylons and thermoplastic olefins (TPOs). Surface-modified versions of wollastonite, however, will continue to be strong market participants. In recent years, new offerings of organosilanes have expanded the use of wollastonite in the rmoplastics. The automotive industry greatly influences the consumption of value-added grades of wollastonite. If automotive manufacturing is growing because of increased sales of new models, for example, development of new plastic parts with mineral reinforcement will require wollastonite. Additionally, other industries tied to automotive manufacturing and sales, such as friction brake products and rubber-based gaskets, will continue their demand for wollastonite as well.

Supply

In the last several years, the North American market has seen the expansion of one traditional supplier, R.T. Vanderbilt, into new grades of both low- and high-aspect-ratio grades, including surface-treated versions. As previously mentioned, Vanderbilt mines and processes wollastonite at its location in Lewis County, New York. This same market has seen the major supplier, NYCO, bring a plant (240 ktpy) onstream in Sonora, Mexico during 1998, only to curtail production a few years later. This leaves NYCO again heavily dependent on its original operation in Essex County, New York (capacity of 110 ktpy).

Imports of wollastonite into North American markets have been active for many years. India and China have introduced high-quality grades to various markets. Currently the Indian material is available in low- and high-aspect-ratio forms, as well as in surface-treated grades. Apparent markets are for thermoplastics and thermoset compositions. Chinese wollastonite has been successfully introduced into metallurgical and ceramics applications. In addition, specialized toll processors of Chinese ore have been successful in

supplying high-aspect-ratio, surface-treated grades for plastics applications. At least one source (Hawley 2004) has reported that there are more than 60 wollastonite operations in China, but most likely less than 10 are active in exporting outside of China or the Asian Pacific basin.

Other wollastonite deposits in North America that may be active in the future can be found in British Columbia and Ontario.

Pricing

The U.S. Geological Survey (USGS) minerals yearbooks for 2002 to 2004 (Virta 2002, 2003, 2004) give prices for wollastonite that range from \$50/t for lump to \$1,700/t for ultrafine, surface-treated wollastonite. Prices for domestically produced wollastonite are

- 200 mesh, ex works, \$226/t
- 325 mesh, ex works, \$273/t
- 400 mesh, ex works, \$303/t
- Acicular, high-aspect-ratio, ex works, \$380/t

Prices for wollastonite from China (all free on board [f.o.b.]) are

- 200 mesh, in bulk, \$80 to \$100/t
- 325 mesh, in bulk, \$90 to \$110/t
- 250 mm lump, \$50 to \$60/t
- 150 mesh, bulk or big bags, \$65 to \$80/t
- 200 mesh, bulk or big bags, \$70 to \$85/t
- 325 mesh, bulk or big bags, \$75 to \$90/t

Historically, the selling prices of wollastonite have been largely determined by the grade versions and the amount of acicularity (as in aspect ratio). Furthermore, because economic wollastonite deposits are not widespread, freight costs for transporting it to users tend to be higher than for more widely found minerals (such as calcium carbonate and silica sand).

The addition of surface-modifying chemicals (coupling agents) can add a significant amount to the price of wollastonite. Some grades have been reported to have prices close to \$2.00/kg as the result of adding chemicals.

Prices reported here are only guidelines used to determine the value of wollastonite as a mineral. Actual prices can depend on contractual terms between suppliers and consumers.

MARKETS

Historically, wollastonite has been used to replace short-fiber asbestos, a use that began its growth as a commercial mineral. Beginning in the 1970s, this growth continued into 2005. Worldwide consumption of wollastonite has significantly increased since its early days. In 1959, world production was approximately 34 kt. By 2004, world production was approximately 575 kt (Virta 2004).

The major uses for wollastonite are fire-resistant products, ceramics, metallurgy, paints and coatings, plastics, friction brake materials, and natural and synthetic rubber (including elastomers).

Fire-Resistant Products

This group of products includes interior and exterior construction boards, roofing tiles, shingles, and slates, shaped and formed insulation, extruded sheets and slabs, corrugated sheets, and siding. The prevalent types are calcium-silicate-based, fiber-cement-based, or asbestos-fiber-cement-based. The typical production methods are slurry, slurry-net, extrusion, or spray processes.

The benefits of wollastonite to these products include

- Improved thermal stability, including fire resistance
- Reinforcement, including microreinforcement

Table 5. Key properties and benefits of wollastonite use in ceramics

Property	Benefit
Mineral chemistry of combined CaO and SiO ₂	<ul style="list-style-type: none"> • Performs like a natural frit • No outgassing • Amount of silica can be reduced, which means better opacity control in matte or opacified glazes
High melting temperature	<ul style="list-style-type: none"> • Lower vitrification temperatures • More efficient melting control
Acicular particle shape	<ul style="list-style-type: none"> • Improved sintering, strength, and thermal expansion control • Stronger body
Firing temperatures	<ul style="list-style-type: none"> • Acts as flux at high temperatures to accelerate even melting at lower temperatures • At lower temperatures, acts as a refractory in matte glazes • Glaze melting improved because lesser amounts of flint added to glaze batch
Source of calcium	<ul style="list-style-type: none"> • Improved color strength
Low LOI	<ul style="list-style-type: none"> • Reduced number of pin-hole defects

- Improved flexural toughness and ductility of Portland-cement-based binders
- Improved water drainage
- Improved dimensional stability and reduced shrinkage and warping
- Reduced cracking and chipping
- Improved green strength

Globally, this end use has been and still likely remains the single largest market for high-aspect-ratio wollastonite.

Ceramics

Wollastonite has had a long history in ceramic use, especially whitewares. It has been used predominantly in ceramic tiles, sanitary ware, tableware, and artware. Within ceramic tiles, wall tile has been the major use area. In this application, wollastonite promotes dimensional uniformity, low shrinkage and warping, strength, low moisture expansion, and fast firing. This last property became crucial when the tile manufacturing trend moved toward rapid-fire bodies. As a result, wollastonite is found in both body and glaze formulations. Table 5 lists the key properties and benefits of wollastonite use in ceramics.

In sanitary ware, wollastonite has demonstrated that its acicular shape can improve the green strength of the body, enhance drying by allowing water vapor to escape more rapidly, and contribute to reduction of fluorine emissions. In a patent granted in 2000, Robinson and Craig claimed that the impact resistance at the drying stage was increased by more than 40% and also noted the improved drying and reduced vitrification temperature.

Metallurgy

Wollastonite's chemical composition enables it to perform as a low-temperature flux when used as part of continuous casting mold powders for steel casting. Another important use for wollastonite is in slag conditioners.

In continuous casting, a ladle containing molten steel is poured into a tundish. When the level of molten steel reaches a specified level, the cast is started by introducing the steel into the mold. A flux

composite powder is pushed onto the molten steel, and because the powder is designed to melt at very high temperatures, it will melt within minutes of contact. This casting flux functions by providing thermal insulation, preventing reoxidation, absorbing nonmetallic inclusions, providing lubrication, and offering uniform heat transfer. Wollastonite is generally 10% to 35% of the flux formula, depending on individual producer formulation. The high melting point of wollastonite (1,540°C) supplies uniform heat transfer and the SiO₂ within wollastonite contributes a silica source.

In continuous casting operations, a mixture of oxides resides on top of the molten steel. This mixture, known as *slag*, helps to condition and purify the steel. This combination of slag conditioners helps to absorb impurities such as sulfur. Wollastonite, as a source of CaO, provides a more effective way of introducing CaO than does lime. Although it is more expensive than lime, wollastonite has a lower melting point and thus liquefies faster than lime.

Tire cord steel is another end use that has been described as benefiting from wollastonite use. Advantages of wollastonite are believed to include modification of Si-Mn deoxidation inclusions to form anorthite inclusions, controlling the oxygen content of the steel, and providing a source of Ca.

The typical grades of wollastonite used in metallurgical applications are the low-aspect-ratio or powder forms, at either -200 mesh or -325 mesh sizes.

Paints and Coatings

Wollastonite has an extensive history in paints and coatings. Starting with the introduction of water-borne polymers to replace linseed oil-based house paints, and continuing into the present with new polymers, the benefits of wollastonite have proved to be numerous.

In architectural or trade sales paints, the low-aspect-ratio powder (or milled) grades are generally used. Improved properties are typically reported as film reinforcement and hardness, tint retention, low-temperature touchup, scrubability, mildew resistance, gloss reduction, and weatherability. In architectural coatings, the milled grades are not surface-modified, and the typical sizes range from -325 mesh to -1250 mesh.

In textured coatings, such as block fillers and stucco coatings, and in aluminized and asphaltic roof coatings, the high-aspect-ratio grades are used. The attraction here is wollastonite's acicular shape, which contributes reinforcement, sag resistance, and microcrack propagation control.

In liquid industrial coatings, especially those designed for anticorrosion performance, wollastonite offers the following improvements:

- Reduced water permeability
- Impact and chip resistance
- Alkaline environment that discourages corrosion
- Intercoat adhesion
- Blister resistance
- Flash and early rust resistance

In these coatings, surface-modified wollastonites are used. Organosilanes are the more common chemistries employed, and amino and epoxy versions dominate. In recent years, the growth of wollastonite in this coatings segment has increased primarily because toxic metallic inhibitive pigments can now be controlled. The synergistic effect of wollastonite with nontoxic corrosion-inhibiting pigments to improve corrosion resistance is well documented.

Industrial powder coatings are categorized into two major groups, functional and decorative. The decorative category consists

Table 6. Processing properties and effects of wollastonite in plastics

Property	Untreated	Chemically Modified
Viscosity	Increase	No effect to moderate increase
Melting flow	Decrease	No effect to moderate decrease
Processing temperature	Increase needed	Little or no effect
Injection pressure	No effect or slight increase	No effect or slight decrease
Flow in mold	Moderate reduction	No effect or slight improvement
Mold shrinkage	Decrease	Decrease
Mold cycle time	Decrease	Decrease

Adapted from Bauer 1990.

mainly of those coatings applied to automobiles, furniture, and appliances. The functional grouping consists of those applied to pipe, such as that used in gas and oil exploration, and certain mechanical housings. Wollastonite is used in both areas, but the largest use is probably in functional powders. In this application, the mineral offers several benefits—control of “orange peel,” gloss reduction and control, film integrity, and durability and weatherability.

Coatings formulators worldwide are increasingly using low volatile organic compound (VOC), waterborne, and high solid-liquid coatings. Wollastonite continues to be selected as one of the filler raw materials as coating formulations evolve.

Plastics

Essentially all the grade types of wollastonite that have been produced have been utilized in plastics. The defining characteristics are aspect ratio, particle size, and surface modification.

Wollastonite is principally a reinforcing functional filler. Several properties of the mineral make it attractive for use in polymer systems: low water absorption, good thermal conductivity, low resin demand, consistent chemistry, and needlelike particle shape.

Table 6 gives processing properties and effects of wollastonite in plastics.

The benefits of wollastonite can generally be categorized by the type of polymer system in which it is incorporated. To discuss benefits, it is important to first note load levels, because the load level of the mineral can vary and depend on polymer type. Table 7 shows the typical load levels of wollastonite in polymers.

Table 8 summarizes the expected benefits of using wollastonite in polymers.

Friction Brake Materials

One of the earliest commercial uses for wollastonite was in friction brake materials. The mineral was found to be a suitable replacement for short-fiber asbestos, which had become strictly regulated—at least in the United States—as a probable carcinogen. Even though wollastonite could not totally replace asbestos, it played a major role for reinforcement. Wollastonite can replace chopped glass in phenolic-based polymer systems. In some formulations the glass replacement percentages can be as much as 15% to 20%, kilogram for kilogram.

One growth area for wollastonite has been in the nonasbestos organic (NAO) friction materials sector. Principal end uses include drum brake applications for passenger cars and light trucks, and brake blocks for heavy-duty truck use.

As in the plastic polymer systems, the key characteristics of wollastonite in friction applications are particle shape, chemistry, mineralogy, high melting temperature, and high temperature stability.

Table 7. Typical load levels of wollastonite in polymers

Polymer	% by Weight
Nylon	22–40
Phenolics	25–45
Polyurethane/polyurea	18–25
Epoxy	15–30
TPOs 25–40	
Polypropylene (PP)	20–40
Polyester	5–35
Polycarbonate	15–20

Table 8. Expected benefits from wollastonite use in polymers

Polymer	Benefits
Nylon	<ul style="list-style-type: none"> • Cost-effective reinforcement versus certain glass fibers • Dimensional stability • Uniform shrinkage • Improved surface appearance • Improved melting flow
Phenolics	<ul style="list-style-type: none"> • Reinforcement • Heat stability • Improved mold cycle time • Improved dimensional stability • Improved physical and electrical properties at high temperatures • Resistance to microcrack propagation
Polyurethane/polyurea	<ul style="list-style-type: none"> • Cost-effective reinforcement for milled glass fiber • Improved surface appearance • Low moisture absorption • Lower shrinkage
Epoxy	<ul style="list-style-type: none"> • Excellent heat stability • Mechanical strength • Cost-effective substitute for chopped glass fiber
PP and TPOs	<ul style="list-style-type: none"> • Overall mechanical strength • Improved balance of impact and stiffness • Improved shrinkage control • Improved melting flow rate and viscosity • Improved mar and scratch resistance
Polyester (including polyethylene terephthalate [PET])	<ul style="list-style-type: none"> • Improved mechanical strength • Heat stability • Nonopacidity
Polycarbonate	<ul style="list-style-type: none"> • Improved flow-line strength • Improved modulus of elasticity • Good thermal resistance • Improved processing behavior

Benefits typically seen with wollastonite are

- Cost efficiency
- Reduced cracking
- Reduced rotor wear
- Improved lining life
- Enhanced processing efficiency
- Improved high-temperature fade and recovery
- Enhanced green strength

Table 9. Primary benefits of using wollastonite in rubber-related elastomers

Property	Benefit	Polymer
Acicular shape	<ul style="list-style-type: none"> • Reinforcement • Stiffness 	Nitrile rubber
Chemistry (including organosilane surface modification)*	<ul style="list-style-type: none"> • Prevention of sponging during press cure 	Fluoroelastomers
Chemistry (with and without surface modification)	<ul style="list-style-type: none"> • Increased modulus • Increased tensile strength • Increase durometer and tear strength • Improved compression set 	Ethylenepropylenediene rubber (EPDM)

* Silane treatment choice is dictated by cure agent used in system.

In some applications, surface-modified forms of wollastonite have been tested and found to improve dispersibility and resin bonding, yielding a stronger matrix. The most commonly used surface-modifying agent has been amino silane.

Other uses within this market segment include piston linings, transmission and clutch plates, and disc brakes.

Natural and Synthetic Rubber (Including Elastomers)

Although wollastonite is not commonly used in rubber-related elastomers, it is important when it is incorporated into these elastomers. For the most part, wollastonite has been used as a reinforcement replacement for fibers with questionable health issues. For instance, in polytetrafluoroethylene (PTFE)-based gaskets, wollastonite replaced asbestos. In other fluoroelastomers, wollastonite can contribute to improved compression set resistance and stability. Typical end use products are resilient rolls, O-rings, seals, and gaskets.

Table 9 summarizes the chief benefits of using wollastonite in elastomers.

Wollastonite, similar to other fillers, is typically incorporated into the mix using the following methods:

- Beater addition—a continuous process where materials are mixed to form a slurry.
- Calendaring—a noncontinuous process carried out in steps. The fully blended mix is then forced between two rolls moving in opposition, and the mix is drawn out as a sheet.

FUTURE OUTLOOK

North American wollastonite producers will continue to place greater emphasis on sales of higher value acicular and surface-treated products in the future (Virta 2003, 2004). Plastics represent the highest potential growth market for domestic producers. Sales of wollastonite for friction products and automotive plastic applications are forecasted to increase slightly as a function of automobile sales. Sales to paint, ceramic, and steel markets should be similar to the last few years, with nearly flat growth. Although China has been the major supplier of lower value wollastonite grades imported into the United States in recent years, these imports may decrease slightly because of increased transportation costs from China and increased prices for Chinese wollastonite. As Wolkem (India) and the Chinese companies improve quality and produce high end, high-aspect-ratio and surface-treated grades, they will provide increased competition to current suppliers of these products. Worldwide consumption of wollastonite is forecasted to increase at a low rate in the near future, as consuming markets slowly expand in response to population growth.

Future challenges to the wollastonite industry in terms of ore quality and product grades are likely to be as follows:

- Providing consistent ore quality in order to achieve proper chemistry and morphology

- Improving ore processing to produce grades that offer consistent particle size distribution and elimination of undesirable contaminants
- Producing grades that are demanded by market needs
- Selecting surface-modifying agents for maximum efficiency
- Understanding completely how minerals (natural and synthetic) must work together in a mixed filler compound to achieve maximum mechanical properties
- Working with consumers to continue development of new grades and applications

Zeolites

Ted H. Eyde and David A. Holmes

Zeolites are crystalline, hydrated aluminosilicates that contain alkali and alkaline-earth metals. Their crystal framework is based on a three-dimensional network of SiO_4 tetrahedra with all four oxygens shared by adjacent tetrahedra. The alkali and alkaline earth cations are loosely bound within this structure and can be exchanged by other cations or molecular water. Most zeolites can be dehydrated and rehydrated without any change in volume. More than 48 natural zeolite minerals have been identified (Tschernich 1992), and more than 100 zeolites have been synthesized. Zeolites have unique physical and chemical properties that are utilized in many important commercial applications.

Though zeolites were first identified more than 200 years ago, it was not until the middle of the twentieth century that their widespread occurrence in sedimentary rocks and economic potential were recognized. Since then, thousands of articles have been published in the technical literature. In the past 40 years, the zeolite mineral group has changed from a museum curiosity to an established industrial mineral commodity.

According to Breck (1974), the important physical and chemical properties of zeolites are

- High degree of hydration
- Low density and large void volume when dehydrated
- Stability of the crystal structure of many zeolites when dehydrated
- Cation exchange properties
- Uniform molecular-sized channels in the dehydrated crystals
- Ability to adsorb gases and vapors
- Catalytic properties

Molecular sieves are materials that can selectively adsorb molecules on the basis of their size, shape, or electrical charge (Clifton 1987). Commercial applications of zeolites are based on the following properties: molecular sieving, ion exchange, adsorption, and catalysis. Most zeolites are molecular sieves, but not all molecular sieves are zeolites. Activated carbon, activated clays, aluminum oxide, and silica gels are also molecular sieves. Activated synthetic and natural zeolite molecular sieve products, however, have displaced many of these substances because of their selectivity.

Potential commercial utilization of zeolites includes hundreds of possible applications. The principal uses at this time are

- Ammonium-ion removal from sewage and industrial effluents, aquariums, and commercial fish farms

- Odor control in animal absorbents, floor and carpet cleaning products, and industrial floor absorbents
- Removal of heavy metal ions from nuclear, mine, and industrial effluents
- Agricultural applications as soil conditioners and animal feed supplements
- Desiccants used to adsorb water vapor in sealed containers and packaging
- Carriers for bacteria and enzymes
- Gas separation
- Catalysis

About 3.5 Mt of natural zeolites were produced and consumed worldwide in 2003. Construction and agricultural applications consumed most of the production, especially in developing countries. Consequently, the total production obscures the significant increases in industrial and commercial applications. The estimated production in North America in 2003 was 42 kt. Most of this was consumed in odor mitigation, aquaculture, agriculture, carriers, desiccants, radioactive barriers, effluent treatment, and other ion-exchange applications. Seven companies in the United States and two in Canada produced the zeolite mineral clinoptilolite. Two companies produced the zeolite mineral chabazite from the Bowie, Arizona, deposit (Eyde 2003).

HISTORY

In 1756, Baron A.F. Cronstedt, a Swedish mineralogist, identified zeolites as a new group of minerals. He named the minerals zeolites from the Greek words *zein* and *lithos*, meaning “boiling stones,” because of the bubbling and frothing achieved by heating the minerals with a blowpipe. There was no real interest in zeolites until the crystal structure of chabazite was determined, followed by the discovery that chabazite selectively adsorbs smaller organic molecules and rejects larger ones, a property described as *molecular sieving*. Following these discoveries, research on the zeolite minerals began in the laboratory of the Linde Company, a division of Union Carbide Corporation, a producer of industrial gases. Initially the researchers at Linde recognized that molecular sieving could be used to separate gases and that this could be used in their air products business. Later they discovered that zeolites could also separate the components of gasoline.

Although the synthesis of zeolites was reported as early as 1862, Barrer (1938) first successfully synthesized analcime-type

zeolites and confirmed them by x-ray diffraction (XRD). He was unable to synthesize either chabazite or mordenite, but instead produced a synthetic zeolite now designated as Linde type A, which is still one of the most commercially important synthetic molecular-sieve adsorbents. The Molecular Sieve Department of the Linde Company commercialized the technology to manufacture Linde type A as well as other synthetic zeolites.

Historically, natural zeolites were considered mineralogical curiosities that mostly occurred as amygdules in basaltic volcanic flows. Subsequently, Regnier (1960) and others discovered large sedimentary deposits of natural zeolites in the western United States. Later exploration identified other, very large zeolite deposits, particularly of clinoptilolite, in the western states and in more than 40 other countries in sedimentary, volcanoclastic rocks and also in hydrothermal deposits.

Synthetic zeolites have supplied many of the markets that natural zeolite products might have served because the synthetics were available first. Natural zeolite producers attempted to displace synthetic zeolites from uses and applications where natural zeolites would have been a better choice, but they lacked the product development and marketing skills needed to compete with the synthetic producers.

In 2003, worldwide production of synthetic zeolites for all applications was more than 2.2 Mt. Synthetic zeolites can be chemically tailored to meet stringent industrial specifications, whereas natural zeolites have a more fixed range of properties. This is changing with the recent introduction of heat-treated and surface-modified natural products. In many applications, natural zeolites have a significant price advantage over synthetics. Also, in some uses their performance is superior to synthetics, such as the use of chabazite from the Bowie deposit as an adsorbent in the treatment of acidic gases.

Mumpton (1983) described Linde's natural zeolite exploration in North America from 1957 through 1962. Shell Canadian began exploration for natural zeolites that could be used as petroleum catalysts in 1962. Mobil Oil Corporation also had a natural zeolite program and mined erionite from the Jersey Valley, Nevada, deposit. Efforts to develop extensive natural zeolite reserves and new products in North America led Anaconda Minerals Company and Occidental Minerals Corporation into major exploration and product development programs between 1974 and 1983. Tenneco Corporation and Phelps Dodge Corporation were late entrants to the zeolite business. None of these companies, however, generated significant sales, and they left the zeolite business.

Neither the oil nor mining companies understood that millions of tons of reserves were not needed to supply a small but growing industrial business whose sales were less than 5,000 tpy. Their lack of marketing expertise was the major cause of their failure. Dow Chemical Corporation, which acquired the molecular sieve business from UOP (the successor company to Union Carbide Corporation), is now the only major corporation in the natural zeolite business. The products sold by Dow are specialty, high-value-added materials that complement their synthetic molecular sieve product lines. The other producers are small entrepreneurial companies that, to their credit, are rapidly developing the products, applications, and marketing skills needed to sell their zeolite products. The natural zeolite business is an industry in transition.

For more than 40 years, natural zeolite minerals have been described as the industrial mineral of the future. The belief that natural zeolites had a multitude of uses and applications was fostered by an enormous outpouring of research that envisioned zeolites for applications in uses from animal absorbents to zeoponics. The potential applications were oversold. Unfortunately, very little of the

research managed to cross over into product development and then into salable products. The brevity of this chapter is intended to provide more easily accessible, useful information and a more concise bibliography, but readers may wish to consult the Zeolites chapters in the 5th and 6th editions of *Industrial Minerals and Rocks* for more detailed information.

GEOLOGY

Mineralogy

The following discussion on mineralogy, chemical properties, and physical properties reviews the works of Breck (1974), Flanigen (1977), and Mumpton (1978), leaders in the study of these complex silicate minerals. Zeolites occur in a variety of geologic settings, mostly as alteration or authigenic minerals, low-temperature–low-pressure minerals in metamorphic systems, secondary minerals in weathered zones, or in veins. Commercial zeolite production is currently limited to authigenic and alteration accumulations in finely crystalline sedimentary rocks. Nine zeolites commonly occur in sedimentary rocks: analcime, chabazite, clinoptilolite, erionite, ferrierite, heulandite, laumontite, mordenite, and phillipsite. Analcime and clinoptilolite are by far the most abundant. All nine of these show a considerable range in silicon:aluminum (Si:Al) ratios and cation contents. Except for heulandite and laumontite, they generally are alkaline and more siliceous than their counterparts in mafic igneous rocks.

Chabazite, clinoptilolite, erionite, mordenite, and phillipsite are the only zeolite minerals with commercial applications today. Erionite, which has been classified as a human carcinogen, has only limited industrial applications. These five are the only zeolites that are abundant in nature and have adequate ion-exchange, absorbency, or molecular-sieving capabilities. Ferrierite and faujasite may also have economic potential, but they are rare and known to occur at only a few localities in the world. It is possible that new technology may result in applications for other zeolite minerals.

Table 1 lists the chemical composition and selected properties of some possible economic zeolites as adapted from Mumpton (1978) and based on the Breck (1974) classification.

Breck (1974) originally listed 34 natural zeolite minerals. An additional 18 natural zeolite minerals have now been identified. The potential commercial application of both natural and synthetic zeolites is a result of their fundamental chemical and physical properties.

The basic structure of zeolites consists of $(\text{AlSi})\text{O}_4$ tetrahedra, wherein each oxygen is shared by two tetrahedra; thus, the atomic ratio $\text{O}:(\text{Si}+\text{Al})$ is 2. The net negative charge of the structure is balanced by exchangeable cations, which are loosely held within the central cavities and surrounded by water molecules. Although their chemical compositions are similar, each mineral has a unique crystal structure and thereby its own physical and chemical characteristics.

Table 2 shows a classification of natural and synthetic zeolites proposed by Breck (1974). Breck's classification is based on the crystal structure of the zeolites in seven groups. In each group, the zeolites have a common specific array of $(\text{AlSi})\text{O}_4$ tetrahedra. Although the same zeolite mineral from different localities may vary considerably in chemical composition, its crystal structure will be nearly identical. Conversely, zeolite minerals with very different crystal structures can have nearly identical chemical compositions.

The dimensions and orientation of void spaces and the interconnected channels in dehydrated zeolites are important in determining the physical and chemical properties. The three types of channel systems identified are a one-dimensional system, a two-dimensional system, and two varieties of three-dimensional, intersecting systems.

Table 1. Typical formulae and physical properties of zeolite minerals and their synthetic counterparts

Zeolite	Typical Unit-Cell Formula	Crystal System	Void Volume, %	Specific Gravity	Channel Dimensions, Å	Thermal Stability	Ion-Exchange Capacity, meq/g*
Analcime	$\text{Na}_{16}(\text{Al}_{16}\text{Si}_{32}\text{O}_{96}) \cdot 16\text{H}_2\text{O}$	Cubic	18	2.24–2.29	2.6	High	4.54
Chabazite	$(\text{Na}_2\text{Ca})_6(\text{Al}_{12}\text{Si}_{24}\text{O}_{72}) \cdot 40\text{H}_2\text{O}$	Hexagonal	47	2.05–2.10	3.7×4.2	High	3.81
Clinoptilolite	$(\text{Na}_4\text{K}_4)(\text{Al}_8\text{Si}_{40}\text{O}_{96}) \cdot 24\text{H}_2\text{O}$	Monoclinic	39	2.16	3.9×5.4	High	2.54
Erionite	$(\text{Na}_2\text{Ca}_6\text{K})_9(\text{Al}_9\text{Si}_{27}\text{O}_{27}) \cdot 27\text{H}_2\text{O}$	Hexagonal	35	2.02–2.08	3.6×5.2	High	3.12
Ferrierite	$(\text{Na}_2\text{Mg}_2)(\text{Al}_6\text{Si}_{30}\text{O}_{70}) \cdot 8\text{H}_2\text{O}$	Orthorhombic	0	2.14–2.21	4.3×5.5	High	2.33
					3.4×4.8		
Heulandite	$\text{Ca}_4(\text{Al}_8\text{Si}_{28}\text{O}_{72}) \cdot 24\text{H}_2\text{O}$	Monoclinic	39	2.10–2.20	4.0×5.5	Low	2.91
					4.4×7.2		
					4.1×4.7		
Laumontite	$\text{Ca}_4(\text{Al}_8\text{Si}_{16}\text{O}_{48}) \cdot 16\text{H}_2\text{O}$	Monoclinic	34	2.20–2.30	4.6×6.3	Low	4.25
Mordenite	$\text{Na}_8(\text{Al}_8\text{Si}_{40}\text{O}_{96}) \cdot 24\text{H}_2\text{O}$	Orthorhombic	28	2.12–2.15	2.9×5.7	High	2.29
Phillipsite	$(\text{Na}_2\text{K})_{10}(\text{Al}_{10}\text{Si}_{22}\text{O}_{62}) \cdot 20\text{H}_2\text{O}$	Orthorhombic	31	2.15–2.20	4.2×4.4	Low	3.87
					2.8×4.8		
					3.3		
Linde A†	$\text{Na}_{12}(\text{Al}_{12}\text{Si}_{12}\text{O}_{48}) \cdot 27\text{H}_2\text{O}$	Cubic	47	1.99	4.2	High	5.48
Linde X†	$\text{Na}_{66}(\text{Al}_{66}\text{Si}_{106}\text{O}_{364}) \cdot 264\text{H}_2\text{O}$	Cubic	50	1.93	7.4	High	4.73

* Calculated from unit-cell formula.

† Linde A and Linde X are synthetic phases.

The character of the water in hydrated zeolite crystals varies, because it can include molecular clustering or direct bonding between the cations and the framework oxygen molecules. The intercrystalline volume that may be occupied by water constitutes up to 50% of the volume of the crystal. The adsorption capacity of a zeolite is generally related to the free space or pore volume as determined by the quantity of contained water when fully hydrated at a standard temperature and humidity.

Adsorption and ion-exchange capacities in both hydrated and dehydrated zeolites are related to the characteristics of the channel openings. The apertures are bounded by oxygen atoms of the connected tetrahedra. The limiting size of the aperture is governed by the size of the rings, which contain 6, 8, 10, or 12 oxygen atoms.

Gottardi and Galli (1985), as a result of their study of zeolite mineralogy, proposed a classification with 23 types of zeolite framework, each corresponding to a particular species of zeolite, and a more specific classification of five framework groups for the natural zeolites.

Figure 1 illustrates the open structure of chabazite showing the enclosed channels.

Chemical Properties

The applications that use natural zeolites make use of one or more of the physical properties, which include adsorption, cation exchange, and dehydration or rehydration. These properties are functions of the specific crystal structure of each mineral, its framework, and its cationic composition.

Adsorption Properties

Crystalline zeolites are unique adsorbent materials. The large central cavity and entry channels of the zeolite are filled with water molecules that form hydration spheres around the exchangeable cations. If the water is removed, molecules having cross-sectional diameters small enough for them to pass through the entry channels are readily adsorbed in the channels and central cavities. Molecules too large to pass through the entry channels are excluded, which results in the molecular sieving property of most zeolites.

Table 2. Breck's classification of zeolites*

Group 1 (S4R)	Group 5 (T5O10)
Analcime	Natrolite
Harmotome	Scolecite
Phillipsite	Mesolite
Gismondine	Thomsonite
Paulingite	Gonnardite
Laumontite	Edingtonite
Yugawaralite	
Group 2 (S6R)	Group 6 (T8O16)
Erionite	Mordenite
Offretite	Dachiardite
Levynite	Ferrierite
Sodalite	Epistibite
	Bikitaite
Group 3 (D4R)	Group 7 (T10O20)
A-Type Zeolites	Heulandite
Group 4 (D6R)	Clinoptilolite
Faujasite	Stilbite
X	Brewsterite
Y	
Chabazite	
Gmelinite	

Adapted from Breck 1974.

* Expressions in parentheses refer to types of zeolite frameworks (e.g., D4R = double 4-ring, T5O10 = a unit of 5 tetrahedra).

Cation Exchange Properties

The exchangeable cations of a zeolite are loosely bonded to the tetrahedral framework and can be easily exchanged and removed by washing with a strong solution of another cation. Crystalline zeolites are very effective ion exchangers. The ion-exchange capacity is basically a function of the degree of substitution of aluminum for silicon in the framework structure. The greater the substitution, the

Adapted from *International Zeolite Association Atlas 2004*.

Figure 1. Open molecular structure of the zeolite mineral chabazite viewed along [010]

greater the charge deficiency, and the greater the number of alkali or alkaline earth cations required for electrical neutrality. Cation-exchange behavior also depends on other factors, including (1) the concentration of the specific cation in the solution, (2) the temperature, (3) the nature of the cation species (e.g., size, charge), and (4) the structural characteristics of the particular zeolite.

Cations can be trapped in structural positions that are relatively inaccessible, thereby reducing the effective ion-exchange capacity. Cation sieving may also take place if the cation in solution is too large to pass through the entry ports into the central cavities. Unlike most noncrystalline ion exchangers, the framework of a zeolite defines its selectivity toward competing ions, and different structures offer different sites for the same cation. The hydration strength of some ions prevents their close approach to the seat of charge within the framework. In many zeolites, ions having a low field strength are more tightly held and are more selectively taken up from solutions than the other ions.

Dehydration/Rehydration

Zeolites exhibit no major structural changes during dehydration; they do exhibit continuous weight loss as a function of temperature and will rehydrate. If the temperature required for complete dehydration is exceeded, the zeolite structure collapses and rehydration cannot occur. Most natural zeolites are thermally stable from 250°C to 400°C (482°F to 752°F). Zeolites with higher silica contents, such as mordenite and clinoptilolite, collapse at temperatures greater than 650°C (1,202°F).

Physical Properties

A zeolite can also be described by its physical properties and performance. The physical properties include morphology, crystal habit, specific gravity, density, color, grain or crystal size, degree of crystallinity, presence of corrosion or etching, presence of contaminants or diluents, and any other descriptive features.

Performance, which is the evaluation of the zeolite for any specific application, entails such characteristics as brightness, color, Brookfield viscosity, Hercules viscosity, surface area, internal volume, particle size and morphology, hardness, abrasion resistance,

wet abrasion durability, thermal expansion, resistance to weathering, and also cation exchange capacity (CEC).

Characterization of any zeolite requires an assessment of the mineralogical properties and the performance characteristics that are believed to be required for the specific use or application. When a specific zeolite is chosen for a commercial application, it must be tested in the environment of the planned use. The efficacy of the zeolite chosen for a use cannot be accurately predicted from properties such as bulk chemistry, zeolite content, or CEC. It is imperative to realize that “one size doesn’t fit all,” meaning that clinoptilolite from deposit A may react differently than clinoptilolite from deposit B.

Origin

Zeolite minerals occur in several geologic settings and can be formed from a variety of starting vitric or lithic materials within an extended range of physiochemical conditions. They occur in rocks deposited in diverse geologic settings and ages. Nearly all the productive deposits in North America occur in sedimentary and volcanoclastic formations of Tertiary age.

Volcanic glass of acid to intermediate composition is the most common precursor for zeolite minerals. Less common precursors include microcrystalline quartz, opal, and feldspars. Nearly all the mineable zeolite deposits in the world occur as zeolitized ash fall tuffs interbedded with lacustrine sediments, zeolitized vitroclastic tuffs in volcanic rocks, and zeolitized vitrophyres and vitroclastic tuffs as a result of hydrothermal alteration.

The development of a specific zeolite mineral depends on interrelated physical and chemical factors. Pressure, temperature, and time are three important factors that produce zeolitic alteration of the vitric precursor. The composition of the vitric component and the composition of the reactive pore water that contains cations such as H^+ , Na^+ , Ca^{++} , K^+ , and H_4SiO_4 are important factors needed to produce zeolitic alteration.

Most zeolites in sedimentary rocks formed from volcanic ash or other pyroclastic material by reaction of the aluminosilicate glass with saline-alkaline pore water. Others originated from the alteration of preexisting feldspars, feldspathoids, biogenic silica, or poorly crystalline clay minerals. Zeolites in sedimentary rocks probably formed by means of dissolution-precipitation reactions.

Earlier formed zeolite minerals can be altered to other zeolite minerals both in near-surface and in deeply buried environments. This is generally a result of changes in the physical parameters within the host rock or changes in the chemistry of the pore water. Natural zeolites have long been known to occur in basaltic rocks as veins and fillings of vugs and cavities. Only much later, because of the introduction of XRD for mineral identification, were they recognized as one of the most common groups of authigenic silicates in sedimentary rocks of volcanic origin.

Based on zeolite geologic setting, mineralogy, and genesis, Sheppard (1973) classified zeolite deposits into the following types:

- Closed system: Deposits formed from volcanic materials in hydrologically closed, saline/alkaline lake systems
- Open system: Deposits formed in hydrologically open, freshwater lake or groundwater systems
- Burial metamorphic: Deposits formed by low-grade, burial metamorphism
- Hydrothermal or hot spring: Deposits formed by hydrothermal or hot spring activity
- Deep marine: Deposits formed in deep marine environments
- Weathered zone: Deposits formed in soils, most commonly from volcanic materials

Closed System

Closed-system zeolite deposits formed in closed or partially closed hydrologic systems that had restricted movement of water out of the basin. The zeolite deposits that formed from accumulations of vitric ash fall tuffs in saline or alkaline lakes are the highest purity sources of the zeolite minerals clinoptilolite, chabazite, and erionite. Sheppard and Gude (1968, 1969b, 1973), starting with the study of a playa lake near Tecopa, California, found that tuffs deposited in such hydrologically closed basins are characterized by a later zonation: fresh ash near the margins of a basin, succeeded inward by a zone of almost complete zeolitization, a zone of analcime, and finally a central core of authigenic potassium feldspar.

The alteration to zeolites depended on high alkalinity and lake brines rich in HCO_3^- . Ash falls of glassy tuff into an alkaline-saline playa or rift lake provided the ideal setting for the formation of high-grade, closed-system deposits. Erionite, chabazite, and phillipsite characterize the saline, alkaline-lake deposits. Zeolitic tuffs in saline-lake deposits generally are from a few centimeters to a few meters thick. They commonly contain monomineralic or mixed zones of the larger pore zeolites erionite and chabazite, which are relatively uncommon in other types of deposits.

Open System

Open hydrologic systems are those in which percolating groundwater moved freely through the host rock. As the groundwater circulated, it was chemically modified by dissolution of reactive materials or hydrolysis. Clinoptilolite and mordenite are the principal zeolites of open-system deposits. The Campi anan Tuff and Neapolitan Yellow Tuff near Naples, Italy, are examples of thick, open-system zeolite deposits. These deposits were formed by alteration of volcanic ash by descending groundwater.

Burial Metamorphic

Zeolites may form in thick volcanoclastic sequences affected by metamorphism. Burial metamorphic deposits, also known as burial diagenetic deposits, are widespread in the Green Tuff region of Japan. With increasing depth, the deposits usually contain zones of (1) fresh ash, (2) alkali clinoptilolite, (3) clinoptilolite–mordenite, (4) analcime, and (5) albite that correlate with the depth of burial and related increases in temperature, pressure, and degree of metamorphism.

Hydrothermal or Hot Spring

The hot spring type includes zeolites associated with hydrothermal alteration, such as those at the East Tintic District, Utah, and especially those associated with hot springs. These occurrences show a vertical zonation and a downward succession of mineral assemblages that appears to correlate with an increase in temperature.

Deep Marine

The most common marine zeolites are clinoptilolite and phillipsite, formed from siliceous tephra and in low-silica basaltic tephra, respectively. Marine zeolites form at low temperatures and may replace as much as 80% of the marine sediments. Deep-sea drilling has found abundant clinoptilolite and phillipsite in cores from many localities in the Atlantic, Pacific, and Indian oceans.

Weathered Zone

Zeolite occurrences within weathered zones are scattered and of little economic significance. Analcime has been reported in alkaline, saline soils in the eastern San Joaquin Valley, California.

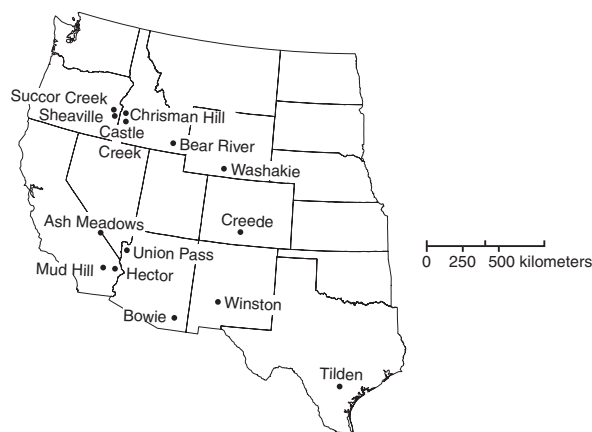

Figure 2. Locations of the producing zeolite deposits in the western United States

DISTRIBUTION OF MAJOR DEPOSITS United States

The western United States has several hundred known occurrences of natural zeolites, including all the zeolite minerals having commercial potential. Resources of clinoptilolite, mordenite, and erionite are extensive, whereas sources of chabazite and phillipsite are more limited. Ferrierite occurrences are restricted to two sites in Nevada; there are, however, no present uses or applications for this mineral. Figure 2 is a map of the western United States showing the locations of producing deposits, important explored but undeveloped deposits, and the principal zeolite minerals that occur in each of them.

Alabama–Mississippi

Low-grade clinoptilolite occurs in the Tallahatta, Nanafalia, Clayton, and Lisbon formations, the Porter Creek Beds, and the Meridian Sand in Alabama and eastern Mississippi (Reynolds 1970). Occurrences in the Porter Creek Beds and the Meridian Sand typically have less than 50% clinoptilolite. Their commercial potential is limited to soil amendments, animal absorbents, and floor sweep products.

Alaska

Mordenite, heulandite, and laumontite deposits occur in the vicinity of Sheep Mountain and Horn Mountain in the Upper Matanuska Valley of Alaska. Zeolitization is the result of burial diagenesis and regional metamorphism of volcanic rocks and related sediments of the Lower Jurassic Talkeetna Formation and the lower units of the Upper Cretaceous Matanuska Formation (Hawkins 1973).

Arizona

Forty-six natural zeolite occurrences have been identified in Arizona; they include open, closed, and hydrothermal deposits. In western Arizona, hydrothermal alteration modified some of the open-system deposits. Most of the open-system zeolites are in Cretaceous to Late Tertiary rocks. Generally, the open-system mordenite and clinoptilolite deposits are in thick sections of vitroclastic ash-flow tuffs and breccias, or clastic tuff units. These zeolite deposits are highly variable in quality because of their high content of fragmentary lithic material.

Figure 3. Chabazite "chains" and clinoptilolite crystals, Bowie, Arizona

Figure 4. Chabazite "chains" and nonfibrous erionite crystals, Bowie, Arizona

Closed-system zeolite deposits occur in many of the Pliocene-Pleistocene intermontane basins in the Basin and Range Province of Arizona. These lacustrine deposits extend from the Wickenburg clinoptilolite deposit in the Big Sandy Basin in the northwest, through the Horseshoe Dam clinoptilolite deposit and the Dripping

Spring chabazite deposit in the central part, to the Bowie chabazite deposit in the San Simon Basin in southeastern Arizona.

Hydrothermal open-system mordenite and mordenite-clinoptilolite occur in Tertiary volcanic rocks in the Oatman and Union Pass areas and the Black Mountains in Mohave County. Mordenite and clinoptilolite occur in the alteration halo surrounding the Oatman gold deposit. This suggests that the zeolitic alteration was produced by the hydrothermal solutions that also transported the gold.

Union Pass Mordenite Deposit. The mine is about 32 km west of Kingman, Arizona, on State Highway 68 at the summit of Union Pass. Union Carbide Corporation shipped several carloads containing 70% mordenite from this deposit (Eyde 1977). A pink mordenite that breaks with a conchoidal fracture replaced a bed of vitrophyre and vitroclastic ash-flow tuff that contains almost no lithic fragments. The mordenite was ground, extruded, and thermally activated. It was sold as Linde AW 300 for the separation of acid gas streams.

Bowie Chabazite Deposit. A series of small strip mines produce chabazite from what was once a nearly continuous, north-west-trending, 15-km outcrop along the San Simon River, 24 km north of Bowie, Arizona. It is the largest known high-purity deposit of chabazite in North America (Sheppard et al. 1987).

The report of Lowe (1875) appears to be the earliest reference to a bedded zeolite deposit in the United States. Lowe reported an outcrop of what appears to be the marker tuff and described it as being composed of the zeolite mineral chabazite. The marker tuff bed was an airborne vitric ash that fell into a saline-alkaline lake and was subsequently altered to zeolite minerals. It is present in a section of Plio-Pleistocene lacustrine beds composed of unconsolidated clays, sand, and gravel.

The marker tuff, which ranges from 22 to 155 cm thick, is composed of varying amounts of chabazite, erionite, and clinoptilolite. It consists of a lower massive bed ranging from 10 to 20 cm thick, overlain by 4 to 135 cm of thin beds. The lower bed, designated as the ore or high-grade bed, contains nearly 100% zeolite minerals. At the northwest end of the deposit, the lower bed is more than 90% chabazite and less than 10% clinoptilolite (see Figure 3). In the central part of the deposit, the lower bed is about 80% chabazite and 10% erionite (see Figure 4). At the southeast end, the lower bed contains 90% chabazite and 10% clinoptilolite. The chabazite in the northwestern part contains more calcium than sodium; in the central part, the percentages of calcium and sodium are about equal; and at the southeastern end, sodium greatly exceeds calcium. The upper thin beds contain 60% to 70% zeolite minerals, principally chabazite and erionite.

The Linde Company acquired the deposit in 1961 and made the first shipment to its molecular-sieve manufacturing plant in North Tonawanda, New York, that same year. This was the first zeolite deposit brought into production in the United States. Several companies have produced more than 20 kt of 80% chabazite from the deposit over the past 42 years. All the production was from the lower massive bed.

The ore bed, which has been explored by more than 3,000 drill holes, has an average thickness of 20 cm. It is mined and carefully cleaned to ensure that all the upper bed and underlying clay have been removed.

The chabazite mined by Dow Chemical from the old UOP and Union Carbide property is processed into extrudates that are activated at 425°C (797°F). The chabazite products are used for natural gas purification, acid-gas drying, hydrogen drying, chlorinated and fluorinated hydrocarbon purification, hydrochloric acid (HCl) removal from by-product hydrogen streams, and the treatment of nuclear effluents. Chabazite from the Bowie deposit was

used to clean up the radioactive effluent from the damaged Three Mile Island nuclear reactor near Middletown, Pennsylvania (King and Opelka 1982; Bostick and Guo 1996).

GSA Resources crushes, screens, and thermally activates chabazite granules at a production plant in Tucson, Arizona. These products are used to remove thallium and heavy metals from mine water. As desiccants, the chabazite products maintain the motility of enzymes and bacteria used to inoculate silage and clean up sites contaminated by hydrocarbons. The upper thin-bedded unit has been used as a lightweight oil-well cement additive.

Horseshoe Dam Clinoptilolite Deposit. This deposit crops out on the east side of the Verde River near Horseshoe Dam, 89 km northeast of Phoenix, Arizona. The principal clinoptilolite bed ranges from 2.6 to 5.3 m thick and crops out continuously for 1.6 km. Most of the deposit is more than 90% white, high-brightness clinoptilolite. The clinoptilolite contains more strontium than calcium and, unlike the clinoptilolite from other deposits, adsorbs oxygen. A 5-t bulk sample was evaluated in a permeability machine pilot plant.

California

Stinson (1988) described the more than 100 known zeolite occurrences in California. Most are in Late Tertiary rocks in open or closed systems in an east-west belt in the Mojave Desert, extending from Mojave-Rosamond easterly about 190 km to Hector and Midway. A second belt of zeolite occurrences extends about 60 km from Tecopa and Shoshone north to the Ash Meadows deposit, northeast of Death Valley Junction.

Zeolite deposits of burial metamorphic or sedimentary origin are present in San Luis Obispo County, where mordenite with clinoptilolite replaced volcanic glass in tuffs of the marine Obispo Formation. Alteration by hydrothermal processes is represented by zeolitization of rhyolitic tuffs and pumice by hot-spring activity near Casa Diablo Hot Springs in Mono County.

Ash Meadows Clinoptilolite Deposit. This deposit is northeast of Death Valley Junction near the California-Nevada border. The zeolitized tuff occurs in an 8-km-long belt in unnamed Late Tertiary sedimentary rocks and extends north into Nye County, Nevada. White to yellowish-white zeolitized ash-flow tuffs and lapilli tuffs typically contain 80% or more clinoptilolite and exhibit high ammonia cation-exchange capacity. The exposed, altered tuff beds strike north-south, generally dip 25° east, and range in thickness from 100 to 130 m. Zeolitization is irregular, leaving some zones unaltered or weakly altered, which requires careful mining control (R.M. Colpitts, personal communication).

Anaconda Minerals Company drilled and developed this deposit with a small open pit, removing and stockpiling about 18 kt of material for bulk-sample testing to initiate production of the clinoptilolite (Santini and Knostman 1979). American Resource Corporation purchased the deposit from Anaconda. Their sources of clinoptilolite were the stockpile and the open pit at the California site. It was processed at the plant at Ash Meadows Rancho in Nevada, where it was crushed, screened, and bagged.

Badger Mining Corporation purchased the deposit, plant, and the assets of American Resource Corporation after the bankruptcy of the parent company, Rea Gold. The company constructed a new processing plant, purchased a packaging company, and began selling products including materials for swimming pool and spa filtration, absorbents, and deodorizers. Clinoptilolite from the Ash Meadows Deposit continues to be used at several sewage treatment plants and nuclear waste processing facilities.

Lake Tecopa Phillipsite Deposit. The Lake Tecopa phillipsite deposit is in the Pleistocene Lake Tecopa basin, between the towns

Figure 5. Phillipsite, Tecopa, California

of Shoshone and Tecopa. The Pleistocene sediments consist mostly of interbedded mudstones and altered to unaltered rhyolitic ash-fall tuffs. These interfinger with coarser clastic sediments toward the margin of the basin. Sheppard and Gude (1968) discovered that a fresh-glass facies occurs along the lake margin, succeeded basinward by a zeolite facies, and then by a central zone of potassium feldspar with sparse amounts of searlesite ($\text{NaBSi}_2\text{O}_6 \cdot \text{H}_2\text{O}$), reflecting the changes in the chemical environment of the lake. Phillipsite is the predominant mineral in the zeolite facies, with lesser clinoptilolite, erionite, and minor analcime and chabazite (see Figure 5). Anaconda Minerals Company conducted an extensive drilling and sampling program on this deposit.

Hector Clinoptilolite Deposit. The Hector deposit is 65 km east of Barstow and 5 km west of Hector siding. The sodium-rich clinoptilolite is light green in color and attrition resistant, which makes it suitable for ion-exchange applications. This deposit produced high-purity clinoptilolite used in the treatment of radioactive effluent at the Hanford, Washington, Nuclear Test Station. Millions of liters of low-level cesium-137 have been processed through the zeolite ion exchangers at Hanford since the 1960s. At the National Reactor Testing Station at Arco, Idaho, steel drums filled with granular Hector clinoptilolite were used in ion columns to recover the radioactive isotopes of strontium and cesium.

Mud Hills Clinoptilolite Deposit. This deposit is about 13 km north of Barstow. It occurs in the Skyline Tuff unit of the Miocene-age Barstow Formation. Sheppard and Gude (1969b) described extensive clinoptilolite mineralization in the Skyline Tuff unit, which was mined at the Mud Hills open pit operated by Occidental Minerals Corporation. In 1982 the mine supplied British Nuclear Fuels Ltd. (BNFL) with high-purity clinoptilolite for ion-exchange applications. Two thousand tons of carefully mined and processed clinoptilolite were shipped to Sellafield, United Kingdom, for use in the BNFL nuclear fuel reprocessing facility. The Skyline Tuff is 3 to

5 m thick at the Mud Hills mine site and typically contains 70% to 90% clinoptilolite that has a high cation-exchange capacity. Since 1982, several successive owners have operated the mine, intermittently supplying clinoptilolite for use as adsorbents and cation-exchange media.

Colorado

The several clinoptilolite deposits in the state include the Creede deposit and the Sand Wash deposit near Craig. The latter is the stratigraphic extension of the Robin's Egg Blue clinoptilolite tuff member of the Washakie Formation in Wyoming (described in that section).

Creede Clinoptilolite Deposit. This deposit is in the Oligocene Creede Formation, about 3 km south of Creede. Altered ash-fall tuff units up to 7 m thick consist of white to light-gray, dense, massive clinoptilolite. The tuffs were deposited in a structural moat around the periphery of the Creede Caldera. Intermittent mining operations have tapped this deposit as a source for regional absorbent markets.

Idaho

Southern Idaho has several large clinoptilolite deposits in production.

Bear River Clinoptilolite Deposit. The Bear River deposit is 10 km from Preston, Idaho. Bear River Zeolite Company, a wholly owned subsidiary of U.S. Antimony Corporation, produces clinoptilolite from a green zeolitized tuff in the Eocene Salt Lake Formation that crops out over a large area in southeastern Idaho. These beds are equivalent in age and physical properties to those at the Mountain Green clinoptilolite deposit in the Salt Lake Formation east of Provo, Utah.

The company produces granular clinoptilolite products for several applications. These include a soil conditioner, cat litter, an algae control product for ponds, and preloaded zeolite fertilizers containing 2.5% nitrogen for use on turf. An absorption product manufactured by the company was successfully used to clean up an anhydrous ammonia spill from a ruptured railroad tank car. Bear River Zeolite continues to expand their customer base, both in the United States and in foreign countries (Anon. 2003, 2004).

Castle Creek Clinoptilolite Deposit. This deposit is 71 km south of Boise, Idaho. Discovered in 1962, it is the largest high-purity deposit of clinoptilolite found by the Union Carbide zeolite exploration program. The soft, fine-grained, ash-fall tuff unit in the Miocene Chalk Hills Formation is altered to fine-grained, white, high-brightness clinoptilolite. Double Eagle Petroleum and Mining Company acquired the deposit in 1976. A paper company evaluated several bulk samples of the clinoptilolite in 1982.

Sheppard (1993a) and Teague Mineral Products subsequently identified an extension of the clinoptilolite bed to the east and southeast along Castle Creek. Teague Mineral Products is actively mining and processing the clinoptilolite for sale in industrial and agricultural applications (G.A. Teague, personal communication).

Chrisman Hill Clinoptilolite Deposit. The Chrisman Hill deposit is 30 km north of Jordan Valley, Oregon. A thick, massive to thin-bedded zeolitized tuff bed occurs in the Miocene Sucker Creek Formation. The deposit consists of high-quality, white to light-gray clinoptilolite, similar in appearance to the Sheaville, Oregon, deposit 11 km to the south. The zeolitized zone is 20 m thick. It contains millions of tons of potential zeolite resources. The deposit, which straddles the Idaho-Oregon border, is mined by Teague Mineral Products to supply its processing plant in Adrian, Oregon. The Chrisman Hill deposit is on a weak hydrothermal alteration trend and shows evidence of hydrothermal alteration as well as obliteration of sedimentary structures (G.A. Teague, personal communication).

Montana

Clinoptilolite is reported from 14 localities in southwestern Montana, all in tuffaceous beds thought to be of Tertiary age and deposited in intermontane basins (Berg and Cox 2001). Clinoptilolite and mordenite occur in Cretaceous tuffs in Beaverhead County.

Grasshopper Creek Clinoptilolite Deposit. This deposit is 16 km southwest of Dillon, Montana. A section of Cretaceous tuffaceous beds is altered to clinoptilolite and minor amounts of mordenite. The cation-exchange capacity of 12 samples collected from the deposit ranges from 0.68 to 1.29 meq/g. Detailed mapping, surface sampling, and three drill holes indicate that this is a minable deposit (Berg and Cox 2001).

Nevada

Nevada has huge resources of zeolites, primarily in two geologic settings: Late Tertiary erionite-clinoptilolite-phillipsite-chabazite ash-fall tuff occurrences of closed system origin in northern Nevada; and thick Tertiary zeolitized ash-flow tuff occurrences of clinoptilolite and mordenite in central and southern Nevada.

Papke (1972) described four Late Tertiary closed-system deposits in north-central Nevada: Eastgate, Jersey Valley, Pine Valley, and Reese River. All the deposits occur in silicic ash-fall tuffs as thick as 5 m in sections of lacustrine sedimentary rocks. The principal zeolite minerals are erionite, clinoptilolite, phillipsite, and chabazite. Mordenite is less common in lacustrine tuff beds. The zeolites were formed by postdepositional diagenesis of vitric volcanic ash that fell into saline, alkaline lakes (Papke 1972).

Pine Valley Erionite Deposit. The Pine Valley deposit is 55 km south of Carlin, Nevada (Regnier 1960). Erionite and phillipsite occur in altered ash-fall tuffs in a thick sequence of Pliocene lacustrine rocks of the Hay Ranch Formation. The principal erionite bed strikes north-south, and dips 2° to 3° east. Union Carbide Corporation has operated the deposit intermittently since 1959 (Papke 1972). The principal zeolitized tuff bed is as much as 2 m thick and typically contains 80% to 90% erionite. Three to five thin beds of high-purity phillipsite occur in bentonitic sediments at the south end of the deposit.

Eastgate Clinoptilolite-Erionite Deposit. This deposit is 88 km east of Fallon, Nevada, and 5 km east of the junction of U.S. Highway 50 and Nevada Highway 2. The beds occur in the Monarch Mill Formation, an Early to Middle Pliocene sedimentary sequence (Papke 1972).

The zeolite beds are of closed-system origin in air-fall tuffs. One or more zeolite beds are present in a zone ranging in thickness from a few centimeters to as much as 5 m. The beds strike north to northwest, are exposed intermittently, and dip easterly at low angles. The most common zeolite associations are erionite and erionite-clinoptilolite accompanied by varying amounts of unaltered glass. Locally, chabazite, phillipsite, erionite-phillipsite, and mordenite are also present.

Union Carbide Corporation staked claims on the deposit in 1957 and dropped them after the Bowie, Arizona, chabazite deposit went into production in 1961. Anaconda Minerals Company staked mining claims on this deposit in 1970 and undertook a detailed exploration program. East-West Minerals, Ltd. later acquired the deposit and built a processing plant nearby. The company attempted to mine the southern part of the deposit, a short distance south of State Highway 2, and process the material for pet litter and absorbent uses. The venture was unsuccessful and the plant was dismantled and removed. In 1997 American Colloid built a state-of-the-art processing plant to produce animal absorbents at the site. Erionite was discovered in the zeolite and the plant was shut down. Badger Mining

Corporation purchased the plant and moved it to Ash Meadows (Eyde 2003).

Jersey Valley Erionite Deposit. The Jersey Valley deposit is 67 km southwest of Battle Mountain, Nevada. Ash-fall tuff beds within Late Tertiary lacustrine sediments are altered to erionite, erionite-clinoptilolite, and erionite-phillipsite-clinoptilolite in the deposit. Papke (1972) described the deposit, which has two zeolitic tuff beds that have minimum thicknesses of 2 to 3.5 m. Mobil Oil Corporation mined these zeolites by underground and open-pit methods from 1965 to 1970 to produce raw material for catalysts used in oil refining and natural gas purification.

Reese River Chabazite Deposit. This deposit is 56 km north of Austin, Nevada. Deffeyes (1959) identified chabazite, clinoptilolite, erionite, and phillipsite occurring in ash-fall tuffs within Miocene or Pliocene lacustrine beds. Eight zeolite beds thicker than 33 cm are present; one is as much as 2.5 m thick (Papke 1972). Union Carbide staked claims on the deposit in 1959 but dropped them after mapping and sampling the deposit.

Lovelock Ferrierite Deposit. This deposit is 17 km northwest of Lovelock, Nevada. Ferrierite-mordenite-clinoptilolite and ferrierite-mordenite occur in altered Miocene or Pliocene ash-fall tuffs. Clinoptilolite is a relatively minor constituent, occurring principally in the upper part of the stratigraphic section.

A remarkable concentration of ferrierite is present in the central part of the deposit. Here, a unit with an exposed thickness of about 17 m contains 75% to 95% ferrierite and minor amounts of mordenite and clinoptilolite. Apparently, this is the largest known deposit of ferrierite in the world (K.G. Papke, personal communication).

Many large deposits of clinoptilolite and mordenite occur in ash-flow tuffs, tuff breccias, and lithic tuffs in Nevada. Most of these occurrences are open system in origin, though some appear to be related to hydrothermal alteration as well. Typically, a large vitroclastic ash-flow zeolite deposit contains 30% to 80% zeolite and has abundant lithic fragments and unzeolitized crystalline and vitric material. Ammonia cation-exchange capacities are usually significantly lower than those in closed-system ash-fall tuffs.

Ash Meadows Clinoptilolite Deposit. An ash-flow zeolite deposit with large resources of high-quality clinoptilolite crops out at Ash Meadows, Nevada. The deposit straddles the Nevada-California border, northeast of Death Valley Junction, California. The deposit is described more fully in the section on California zeolites. The Nevada portion of the deposit includes a large resource of green clinoptilolite in Pliocene ash-flow and lapilli tuffs.

Beatty Mountain Mordenite Deposit. This deposit crops out on the west side of Beatty Mountain. Thick greenish-white mordenite beds are interbedded in a section of Pliocene ash-flow tuffs. Samples collected by Union Carbide contained from 70% to 85% mordenite.

New Mexico

There are two productive clinoptilolite deposits in New Mexico.

Buckhorn Clinoptilolite-Chabazite Deposit. This deposit is 58 km north of Silver City, New Mexico, and 2.5 km south of the community of Buckhorn on the west side of Duck Creek Valley. Two clinoptilolite beds crop out in the Plio-Pleistocene Cactus Flat beds. The lower bed is 1 to 1.6 m thick with 70% to 90% clinoptilolite and chabazite. The upper bed is about 30 cm thick and contains 60% clinoptilolite and a trace of erionite (Eyde 1982; Sheppard et al. 1987). Zeotech Corporation mined and shipped a few truckloads of clinoptilolite to their processing plant at Tilden, Texas.

Cuchillo Negro Clinoptilolite Deposit. The most productive clinoptilolite deposit in New Mexico is about 300 km south of Albuquerque and 6.5 km south of Winston. The deposit is in a 180-

to 240-m-thick section of interbedded tuffaceous and conglomeratic rocks that are 29 million years old (McIntosh, Kedzie, and Sutter 1991); it crops out along Cuchillo Negro Creek at the south end of the Winston graben. The zeolite bed being mined by the St. Cloud Mining Company is 4.4 to 10.7 m thick and contains 50% to 85% clinoptilolite that is more attrition resistant and has higher potassium content than most other clinoptilolite. In 2002 St. Cloud Mining Company mined and processed 14.5 kt of clinoptilolite products. These were sold into consumer, industrial, and agricultural markets throughout North America (Barker et al. 2003).

Oregon

Several natural zeolite deposits with economic potential occur in eastern Oregon. The zeolite occurrences in marine sedimentary rocks in western Oregon have no obvious commercial potential.

Durkee Chabazite Deposit. This deposit is in a closed basin near the community of Durkee, Oregon, 165 km northwest of Boise, Idaho. An area of about 18 km² is underlain by chabazite, clinoptilolite, erionite, and authigenic feldspar. Vitric ash fell in a Miocene saline alkaline lake and formed zeolite minerals at low temperature and pressure. The zeolitized ash-fall and reworked tuffs and one ash-flow tuff are interbedded with diatomite, mudstone, sandstone, siltstone, and conglomerate. The U.S. Geological Survey made several investigations of the deposit (Sheppard and Gude 1969a, 1980; Gude and Sheppard 1986, 1993).

Anaconda Minerals Company, Occidental Minerals Corporation, and Filtrol Corporation explored the deposit and identified several promising target areas containing possible large tonnages of chabazite, but their exploration results remain unknown.

The Harney Basin Clinoptilolite Deposits. The Harney-Malheur Basin is about 40 km south of Burns, Oregon. Near-surface Miocene tuffaceous rocks constitute an enormous zeolite resource. The principal mineral is clinoptilolite with lesser erionite, chabazite, phillipsite, and mordenite on the basin margins. The principal mineralized zone underlies an area of more than 20 km² (Sheppard 1993c). A massive clinoptilolite bed 20 m thick underlies much of the basin. Toward the southern margin of the basin, the clinoptilolite-rich tuff interfingers with thinner beds of erionite, chabazite, and phillipsite. The zeolite deposits of the Harney Basin formed as a result of diagenetic alteration of ash-fall tuffs and reworked tuffaceous fluvial sediments within a closed hydrologic system.

Rome Erionite Deposit. The Rome deposit is 60 km west of Jordan Valley, Oregon, near the Owyhee River and Crooked Creek in an area dissected by steep-walled canyons (Sheppard and Gude 1983, 1993b). The deposit has an extensive resource of high-purity erionite, mordenite, and mixed mordenite-clinoptilolite. The zeolites occur in several tuffaceous members of the Rome beds, a 130-m-thick Miocene fluvio-lacustrine sequence. Two zeolitized beds in the lower member initially appeared to have significant commercial potential. Each bed is about 3 m thick and contains 50% to 70% erionite. The fibrous morphology precludes its use in commercial and consumer applications.

Sheaville Clinoptilolite Deposits. The Sheaville deposits are 19 km north of Jordan Valley, Oregon, between U.S. Highway 95 and the Oregon-Idaho border. These deposits are present in at least 10 km² where the westward-flowing Succor Creek crosses the state border and the axis of a north-south trending anticline. The Sheaville District has large resources of high-quality clinoptilolite available for mining.

The Sheaville clinoptilolite sequence is in the Miocene Sucker Creek Formation, a lacustrine unit of interbedded tuff, zeolitized tuff, bentonite, and carbonaceous siltstone (Almner and Grim 1990; Sheppard and Gude 1983, 1993c).

As many as five thick, massive units of white to light gray, zeolitized ash-fall tuff crop out in the area. Clinoptilolite is the predominant zeolite, with trace amounts of mordenite. Zeolitization is most intense near the axis of the anticline (Holmes 1990).

Zeolite production by the Norton Company has been confined to the uppermost clinoptilolite bed on the western flank of the anticline. The bed is well exposed several hundred meters east of U.S. Highway 95, near the western edge of the zeolitized area. The lowest clinoptilolite bed is the thickest in the district and crops out on the south side of Succor Creek. It is as much as 22 m thick and consists of white to light-gray massive clinoptilolite. Occidental Minerals Corporation drilled this bed between 1977 and 1981 and opened a large test pit near the anticline axis in 1982.

Succor Creek Clinoptilolite Deposits. These deposits are 13 km north of Rockville, Oregon, and just south of Succor Creek State Park. Several deposits of white to light gray, massive, and sandy zeolitic tuff occur in the Miocene Sucker Creek Formation along the lower part of Sucker Creek, both within and downstream from the state park (Almner and Grim 1990).

The beds contain 30% to 70% clinoptilolite and are up to 26 m thick. These occurrences have a hydrothermal alteration overprint and generally are more variable and less altered than the Sheaville and Chrisman Hill deposits (Altaner and Teague 1993). Teague Mineral Products operates an open pit in the lower Succor Creek area to extract clinoptilolite for pet litter and odor control uses.

South Dakota

The only important occurrence of natural zeolites in South Dakota is the Sheep Mountain Table clinoptilolite deposit.

Sheep Mountain Table Clinoptilolite Deposit. This deposit is on the Pine Ridge Indian Reservation near Rockyford, South Dakota. An extensive resource of clinoptilolite occurs in zeolitic tuff in the Rockyford Member of the Miocene Sharps Formation, which caps hills and mesas in the badlands on the Pine Ridge Indian Reservation and adjacent Badlands National Monument to the north (Raymond 1986). The zeolite-rich tuffs are as much as 33 m thick and are of open-system genesis. The clinoptilolite content is in the 50% to 60% range, with ammonia cation-exchange capacity values of 0.6 to 1.40 meq/g (Desborough 1989). The deposit is not developed.

Texas

Texas has large resources of clinoptilolite in two regions (Walton, et al. 1972). In south Texas, a belt of zeolitized ash-fall tuff in the Wellborn and Yegua formations of the Eocene Jackson Group of Gulf Coast sediments extends from Zapata County on the Rio Grande River northeasterly, cropping out west of Tilden in McMullen County, and extending east toward the Gulf of Mexico.

Large resources of clinoptilolite also occur in zeolitized ash-fall tuff beds and tuffaceous sediments in the Oligocene Tascotal Formation in the Trans-Pecos region between Presidio and Marfa (Bostros 1976; Walton and Henry 1979).

Tilden Clinoptilolite Deposits. A cluster of clinoptilolite deposits is located 8 to 13 km west to northwest of Tilden. The Buck Martin pit has a flat-lying, white, flaggy, zeolitized ash-fall tuff 3 m thick containing as much as 80% clinoptilolite. The nearby Kuykendall pit has a 4-m-thick bed containing 90% clinoptilolite. The Tilden Area zeolite resources are large, but they occur in scattered deposits. Zeotech Corporation mines and processes clinoptilolite into pet litter, swimming pool filtration media, a turf treatment product, material for ion-exchange applications, and other generic absorbent products (Eyde 2003).

Utah

Zeolite occurrences have been identified at 56 localities in Utah. Six sedimentary clinoptilolite deposits may be minable.

Trenton Clinoptilolite Deposit. The Trenton deposit is located along the west side of Cache County about 35 km north-northwest of Logan, Utah, and extends northward into Idaho. It is a zeolitized ash-fall tuff in the Tertiary Salt Lake Formation. (See the description of the Bear River Clinoptilolite Deposit in the Idaho section [Mayes and Fripp 1991].)

The zeolitized green, fine-grained tuffs constitute a very large potential resource, containing as much as 70% clinoptilolite. It is a high-potassium clinoptilolite deposit, similar to the Mountain Green occurrence to the south.

The Mountain Green Area in Morgan County contains estimated zeolite resources greater than 240 Mt. The clinoptilolite content commonly is 50% to 80%.

Wyoming

Natural zeolites have been described at 88 locations in Wyoming. Potentially minable zeolites, in order of importance, include clinoptilolite deposits in the Washakie Basin, along Beaver Rim, and on Lysite Mountain (Harris and King 1990).

Washakie Basin Clinoptilolite Deposits. This deposit is about 73 km east of Rock Springs, Wyoming. Roehler (1973) discovered and described the Washakie Basin clinoptilolite. The report identified clinoptilolite and mordenite in tuffs of the Laney Shale Member of the Green River Formation and in tuffs in the Robin's Egg Blue tuff bed of the Adobe Town Member of the Washakie Formation. The Robin's Egg Blue bed is a light blue to greenish-blue zeolitized ash-fall tuff altered to 50% to 90% clinoptilolite. Extensive drilling and testing indicate that the clinoptilolite is suitable for a wide range of applications, including nuclear waste cleanup.

Rocky Mountain Energy Corporation (now Union Pacific Resources-Minerals) attempted to develop clinoptilolite in its checkerboard sections on the north rim of the Washakie Basin between 1978 and 1983. The venture also produced limited tonnages of the blue-green clinoptilolite for cat litter and other deodorant applications (Hulbert 1987).

U.S. Zeolite Corporation subsequently leased the Rocky Mountain Energy fee lands and claims and obtained state mineral leases covering other promising clinoptilolite occurrences along the rim. The company is now doing testing and marketing studies and has produced small tonnages of clinoptilolite for absorbent and industrial uses (T. van Fleet, personal communication). Adwest Minerals International acquired U.S. Zeolite and now controls the deposit.

Beaver Rim Clinoptilolite-Chabazite Deposit. The Beaver Rim deposit is near Riverton, Wyoming. Several beds of clinoptilolite, mixed clinoptilolite-chabazite and clinoptilolite-erionite occur in ash-fall tuffs in the Eocene Wagon Bed Formation in the district, in Fremont County (Boles 1968; Van Houten 1964). U.S. Energy Corporation produced and sold small tonnages of clinoptilolite during the 1980s to western aquacultural markets and to an experimental sewage treatment plant developed by ATEC Inc. in Riverton.

Zeolites Outside the United States

Natural zeolites are being produced in 37 countries and occur in another 28. Production is intermittent and figures are unreliable (Harben and Bates 1990). The major producing countries are China, Cuba, Japan, the United States, Hungary, and Bulgaria. Smaller tonnages come from Australia, Germany, New Zealand, Italy, and South Africa. More new discoveries of natural zeolite minerals are being reported. Most of the discoveries are minor

occurrences that will never be put into production because of their impurities or size. Many of the deposits being mined in developing countries supply crushed and quarried products used in agriculture and construction. Only the deposits that are in production or are being explored are described here. For more comprehensive information on the distribution of zeolites, refer to the 5th and 6th editions of *Industrial Minerals and Rocks*.

The following countries are also known to have zeolite deposits that are not being explored or developed:

- | | |
|--------------|--------------------|
| • Algeria | • Namibia |
| • Austria | • The Netherlands |
| • Chad | • Pakistan |
| • Denmark | • Papua New Guinea |
| • Egypt | • Philippines |
| • Iran | • Puerto Rico |
| • Israel | • Senegal |
| • Jamaica | • Spain |
| • Kenya | • Switzerland |
| • Malawi | • Taiwan |
| • Mali | • Tunisia |
| • Mauritania | • Uganda |
| • Mongolia | • United Kingdom |

Cuba has done extensive research on the agricultural applications for natural zeolites. In fact, most of the natural zeolite research was done in the communist Eastern bloc countries before the collapse of the Soviet Union. Since then there has been a significant transfer of technology from these countries to entrepreneurial companies based in the capitalist countries for commercialization. One of the best examples is the ZELflocc technology for sewage treatment developed in Hungary and licensed by Zeolite Australia. The company now has 14 wastewater treatment plants in operation using the process (Eyde 2000).

In the case of China, Russia, and many other countries, the information is incomplete and possibly inaccurate. Some of the information has been provided verbally, and may be lacking in credible documentation. It is presented here, nevertheless, to provide the most complete reference on natural zeolite mineralogy, occurrences, uses, and applications. Certainly, in the future, other deposits will be discovered and brought into production from deposits in countries that are not mentioned in this chapter.

Argentina

Cristamine SA processes and sells clinoptilolite from local sources for use in animal feeds.

Australia

Natural zeolites occur in Paleozoic rocks in the Drummond Basin, Queensland, and in rocks from Late Carboniferous to Tertiary age in New South Wales. Production of zeolite from New South Wales is limited to two producers with a total production of about 7 ktpy. Zeolite Australia Ltd. has produced and sold clinoptilolite from sources in New South Wales since 1988. Zeolite Australia operates the Escott mine and processing plant, 5 km southwest of Werris Creek, New South Wales. Zeolites from this deposit are being used in many parts of Australia and some are being exported. The production is about 4 ktpy (Anon. 2004).

A number of reports have been published on the occurrence of natural zeolites in New South Wales (Holmes and Pecover 1987; Crossley 2002; Cullen 2004).

Curumbin Sand and Gravel Pty Ltd. operates a zeolite mine at Willows, in central Queensland. Currently, production is 3 ktpy.

Supersorb Environmental NL processes zeolite through its crushing and screening plants at Springvale and Duaringa, central Queensland (Anon. 2004).

Bulgaria

Extensive zeolite deposits occur in Bulgaria. The principal deposits are in the Srednogorian zone south of the Balkan Mountains and the Eastern Rhodopes (Gottardi and Obradovic 1978).

In the Rhodopes, large deposits of clinoptilolite and mordenite occur in the Oligocene rhyolitic pyroclastic rocks. A bed of white clinoptilolite 35 m thick crops out near the village of Perperek. A clinoptilolite bed 110 m thick occurs in a section of Oligocene tuffaceous sediments between the villages of Beli Plast and Mest.

Clinoptilolite has been produced from the deposits in the Eastern Rhodopes for many years. Bentonite EAD in Kardjali operates a surface mine at White Hill that has a capacity of 50 ktpy. Clinoptilolite production over the past 10 years has ranged from 2 to 45 ktpy. The clinoptilolite products are used in detergents, water filtration, food additives, and gas treatment, and as soil conditioners and fertilizer carriers.

Canada

Sedimentary zeolites that were discovered in Tertiary basins in interior British Columbia during the 1980s are now being brought into production. Clinoptilolite and heulandite occurs in Tertiary sedimentary rocks in the Cache Creek, McAbee, and Battle Creek areas. The rhyolitic tuffs of Eocene age contain clinoptilolite beds that range from 1 m to 6 m thick (Read 1987).

Several companies produce clinoptilolite from deposits in the Princeton and Cache Creek basins in British Columbia. Canmark International Resources explored and began clinoptilolite production from a deposit in the Princeton Basin. Highwood Resources produces clinoptilolite–heulandite from a deposit in Cache Creek. The zeolite is processed into agricultural products at Rocky Mountain House, Alberta.

China

Clinoptilolite and mordenite deposits occur at a number of locations throughout China. Six producers are reported in the country. Most of the production is from deposits in altered volcanic rocks of open-system origin. Most of the estimated 3 Mtpy of zeolite produced in China goes into pozzolanic applications. The balance goes into agricultural and industrial applications. Chabazite, phillipsite, and erionite are reported in closed-system settings in interior desert plays.

The U.S. Geological Survey estimates that the worldwide (not including China) production of zeolites in 2002 was 3.5 Mtpy. Thus, the estimated Chinese zeolite production is nearly equal to production in the rest of the world. Assuming that the production estimate is close to being correct, China is the world's largest producer of zeolite minerals.

Cuba

Exploration for natural zeolites that began in the 1970s has developed resources of more than 300 Mt, principally clinoptilolite–heulandite and mordenite (Griffiths 1987; Fuentes and Gonzales 1991). Cuba may be the world's second largest producer of zeolites. In 1994 the Cuban International Marketing Firm for Industrial Minerals SA (CIMTEC) reported exports of 100 kt for agricultural applications.

There are at least 25 zeolite deposits in Cuba. Most deposits consist of altered volcanic tuffs within volcanogenic sedimentary rocks of Lower Cretaceous and Middle Eocene age.

Clinoptilolite–heulandite resources include the Tásajeras-Piojillo, San Antonio, Najasa, and La Pita deposits. The Palmarito and San Cayataro deposits are nearly pure mordenite. Five plants having an overall annual production capacity of 500 kt are currently processing zeolites mined from four deposits (Anon. 1988).

France

Exploration in France for economic zeolite deposits began in 1989, principally in the Massif Central region. Three areas of promising discoveries include clinoptilolite and heulandite in ash-fall sediments of the Limagne Bourbonnaise Basin and phillipsite in ash-pumice tuffs originating from stratovolcanoes of the Cantal and Mont-Dore regions (Rocher et al. 1991).

Clinoptilolite occurs in Upper Cretaceous marls and chalks in the Anjou District on the west side of the Paris Basin. It has also been detected in Paleogene marine sediments of that basin. Analcime and clinoptilolite are present in sediments containing volcanic debris in the Limagne de Clermont-Ferrand (Gottardi and Obradovic 1978).

No production has been reported from these deposits, although Materials de la Mediterranee SA processes zeolites and Poortershaven processes zeolites for animal feed at its plant in Poissy, France.

Germany

Rocks containing zeolite minerals are mined from several deposits in Germany. Nearly all the production is used as pozzolan. Clinoptilolite occurs in Upper Cretaceous marls and marly limestone. It is used in the manufacture of cement at plants near Hannover and surrounding areas in northwest Germany.

Quaternary volcanic rocks in the Bonn and Laacher See areas of the Rhine region contain zeolitized pumiceous tuffs that are mined for pozzolans. The zeolite minerals include chabazite, phillipsite, and analcime.

The largest producer of zeolites in Germany is Hans G. Hauri Mineralstoffwerk in Botzingen-Oberschaffhausen. The company produces 150 ktpy of a zeolitically altered phonolite that contains 40% zeolite. The principal minerals are natrolite, scolecite, and lesser amounts of mesolite, thompsonite, and phillipsite. Nearly all the production is sold as a pozzolan. The fines are sold to vineyards in the Rhine and Mosel valleys where they are used as a highly effective nontoxic fungicide. The fines are also used in personal care products.

Franke & Schulte GmbH, H.J. Schmidt Mineraltechnik GmbH & Co., and Carl Spaeter GmbH custom process and sell zeolite products.

Greece

The Institute of Geology and Mineral Exploration and the Institute of Geological and Mining Research identified zeolitically altered tuffs on the islands of Milos and Polyaeos, and also in the Evros Area in mainland Greece (Tsirambides, Filippidis, and Kassoli-Fournarakis 1993; Tsolis-Katagas and Katagas 1990).

Silver & Baryte Mining Company SA began producing zeolite from the Evros deposits in 1996. The deposits are estimated to contain 6 Mt of 75% clinoptilolite. The company produces five clinoptilolite products that are used as supplements in animal feeds, soil amendments and conditioners, water treatment, animal litter, and absorbents.

Hungary

Major deposits of clinoptilolite and mordenite occur in the zeolitically altered Sarmatian rhyolitic tuffs and ignimbrites in the Tokay

Mountains. The zeolite deposits contain 65% to 95% clinoptilolite (Gottardi and Obradovic 1978).

Clinoptilolite is mined from the Ratka deposit and mordenite is mined from the Bodrogkeresztúr deposit. Hungarian production of natural zeolites was estimated to be 40 to 50 kt in 1987 (Griffiths 1987). In 1997 the production was estimated to be 15 kt.

The principal markets for the clinoptilolite products are feed supplements, products for ammonia–nitrogen removal from aquariums, and cat litter. The specialty products sold in Hungary include a deodorizer for wineries, a kitchen scrubbing compound, and a bathroom cleaning and deodorizing product.

Indonesia

Altered volcanic rocks hosting natural zeolites have been identified on several islands in Indonesia. Several recently developed clinoptilolite deposits are providing zeolite products to regional agriculture and aquaculture industries.

Eastmet Ltd. is developing a clinoptilolite deposit at Mt. Ratai and Tarahan in Lampung Province, Sumatra. Another zeolite deposit 20 km south of Panjung, the major port in Lampung Province, is currently producing crushed and screened clinoptilolite product for use in local aquaculture markets. Clinoptilolite and mordenite are produced from a mine on Java and made into products for sale throughout the eastern Pacific Rim.

Italy

Italy has a great number of zeolite occurrences, ranging from the extensive Neapolitan and Campanian zeolitic tuff systems in central Italy near Naples and Rome to zeolites of marine origin in Sicily. Burial metamorphic and hydrothermal origin zeolitic tuffs occur in the Apennines in northern Italy.

The Neapolitan Tuff, the Campanian Tuff, and equivalent volcanic formations crop out over extensive areas around Rome and the Gulf of Napoli. The deposits in these tuff beds are the economically important ones in Italy. Both tuffs contain phillipsite and chabazite in beds from 20 to 120 m thick and have been used since Roman times as dimension stone (Aiello 1993). Both are sources of raw materials used in a wide range of industrial and agricultural applications. Coarse pyroclastic rocks from the Roccamonfina Volcano, about 50 km northwest of Naples, contain significant amounts of chabazite and analcime and are quarried as building stone.

Tuff layers in a thick Quaternary pyroclastic sequence from the calderas of the Vulcano Laziale, about 20 km east of Rome, contain chabazite and phillipsite. Chabazite occurs in altered zones in tuffs and ignimbrites within Quaternary calderas in the Latium region near Rome. Lenzi and Passaglia (1975) described chabazite occurrences at Bracciano Lake that constitute more than 50% of the tuff.

Mineraria del Mediterraneo Italia Srl. produces 4 ktpy of chabazite and phillipsite from its mine in Sorano, Grosseto, about 100 km north of Rome. Its zeolite products are used in water treatment and animal feeds.

Japan

As a leading producer of natural zeolites, Japan is also a world leader in development and application of zeolite technology. It utilizes zeolites for a wide range of agricultural, industrial, and consumer uses. Annual production has ranged from 60 to 100 kt since the mid-1960s. Torii (1978) and others studied Japanese natural zeolite deposits and described their uses and applications. Zeolites occur in rocks ranging from Triassic to Quaternary in age, but the majority is in Miocene pyroclastic and volcanogenic

sedimentary rocks. Most zeolite occurrences in Japan are related to low-grade metamorphism. Many occurrences show zonation typical of burial metamorphism; others show zoning caused by hydrothermal alteration related to igneous intrusion.

Clinoptilolite and mordenite are the only zeolite minerals mined in Japan. Both minerals have been used for industrial and agricultural applications since 1949. Both minerals occur in the Green Tuff belt of metavolcanic rocks, but clinoptilolite is the most important zeolite mineral in Japan.

Eighteen companies produce between 140 and 160 kt per year of natural zeolites in Japan. Only eight produce significant quantities, and only three produce more than 10 ktpy. Clinoptilolite is produced at the Itaya mine in Yamagata Prefecture, Honshu, and processed by the Zeaklite Chemical & Mining Company, Ltd. for use in agricultural and other applications. The company produces at least 60 ktpy and is Japan's largest zeolite producer. Sun Zeolite Ind. Co., Ltd. produces clinoptilolite from its deposit in Akita Prefecture for agricultural use (Griffiths 1987). Nippon Kasseihakudo Co., Ltd. produces by-product clinoptilolite from its calcium-bentonite operations. The company also produces synthetic zeolite A using clinoptilolite as the raw material.

Smaller Japanese producers include Shinshinden Development Co., Ltd. (mordenite and montmorillonite), Hamamichi Kohsan Co., Ltd. (zeolite and montmorillonite), and Asahi Kasei Kogyo Co., Ltd. (mordenite) (Griffiths 1987). Other markets for Japanese zeolites are adsorption and water treatment.

Korea

Clinoptilolite-heulandite and mordenite deposits occur in both countries on the Korean peninsula. In the Democratic People's Republic of Korea, zeolites occur in Pliocene acid volcanic rocks in the Kilcho-Mjong Chong Province, which is in the northeastern part of the Korean peninsula. Clinoptilolite- and mordenite-rich tuffs also occur in the northeastern part of the province, near the villages of Han Zin and Phoha. Two clinoptilolite deposits in the southwestern part of the province contain clinoptilolite, heulandite, phillipsite, and chabazite (Han et al. 1985).

Clinoptilolite and mordenite occur within altered Miocene tuffs and tuffaceous sediments in the Guryongpo Area in the Republic of Korea (Noh and Kim 1982). The Kuryong mine at Kuryong and the Dalsin mine at Tonghai, both in Kyongsangbuk Province, produce 110 ktpy of clinoptilolite products.

Mexico

Natural zeolites occur in altered Tertiary volcanics and lacustrine beds in Mexico. A chabazite-erionite bed 12 to 14 cm thick occurs in Plio-Pliocene lacustrine beds in the extension of the Santa Barbara Valley south of Agua Prieta, Sonora. The deposit is nearly identical to the Bowie, Arizona, chabazite deposit 120 km to the north, both in extent and mineralogy. The erionite from the deposit was tested for use in petroleum-cracking catalysts and radioactive waste treatment.

A clinoptilolite-mordenite deposit near Rancho Tetuache, 20 km south of Arizpe, Sonora, is a zeolitized vitroclastic tuff more than 200 m thick that contains 80% to 90% combined clinoptilolite and mordenite. A 20-ton bulk sample was used to treat the runoff from cattle feed lots. There are several other zeolite occurrences in the state of Sonora.

Zeolite deposits occur at Etla and San Antonio, Oaxaca, and in the states of San Luis Potosí, Puebla, and Guanajuato. Over four centuries, large buildings in southern and central Mexico, including a cathedral at Oaxaca, have been built of clinoptilolite-mordenite-rich tuffaceous rocks because of its strength, workability, and durability.

Geoexplorers International began processing test lots of clinoptilolite at a toll-processing facility in the city of San Luis Potosí. The clinoptilolite is mined from the Escalera deposit in the state of San Luis Potosí and the Almandina deposit in the state of Guanajuato (Eyde 2000).

New Zealand

Natural zeolites are abundant in the Waitemata Group, an Early Miocene sedimentary sequence in Auckland Province. The main part of the group consists of sediments where clinoptilolite and chabazite occur in interbedded volcanoclastic rocks. NZ Natural Zeolite has begun producing zeolite products. It supplies a range of products used as adsorbents in ion-exchange applications and fertilizer carriers (Eyde 2000).

Republic of South Africa

Clinoptilolite is produced from altered Jurassic volcanic rocks at the Pratley Perlite Mining Co. Pty. Ltd. mine at Hluhluwe in what is now the province of KwaZulu-Natal. Both clinoptilolite and mordenite are associated separately with perlite and white calcium bentonite, which are also mined and processed (Griffiths 1987).

Romania

Large deposits of clinoptilolite and mordenite occur in Late Tertiary tuffs in the Transylvanian Basin and in the Precarpathian zone. These tuffs are commonly tens of meters thick and have been used for hundreds of years as building stone. They are of open-system origin and offer significant economic potential (Istrate 1980).

Russia

Research done in the former Soviet Union developed a wealth of potential applications for zeolite minerals. In fact, the Soviet Union was probably ahead of Japan in technological capability to develop new zeolite-based products, but the Soviets, unlike the Japanese, did not have the product development and marketing expertise needed to sell their products. Most of the Russian zeolite production is used in agricultural applications. The widespread radioactive contamination of soil and water caused by the Chernobyl nuclear reactor disaster required the development of decontamination techniques that utilized natural zeolites (Chelishchev 1993).

Gottardi and Obradovic (1978) presented a cursory overview of Soviet natural zeolite occurrences and geology. Tsitsishvili (1988) summarized earlier information on Soviet zeolite research and commercial application, including zeolite synthesis.

Salavatnefteorgsintez and Bashneftekhinzavody I Shimbay Special Chemical Catalysts produce zeolites in Russia. Both of these plants are in the Bashkortostan region. Production at Bashneftekhinzavody is about 8 ktpy of clinoptilolite used as a pozzolan in cement.

Serbia

Zeolites occur in open, hydrothermal, and burial metamorphic deposits in Serbia. Clinoptilolite and mordenite are present in altered pyroclastic rocks of Triassic to Late Tertiary age. Clinoptilolite is mined for local use, mostly for agricultural, from several deposits.

Slovakia

Natural zeolites were discovered at Nizny Hrabovec in eastern Slovakia in 1976. Reserves of more than 7 Mt ranging in grade from 40% to 60% clinoptilolite have a mean cation-exchange capacity of 0.78 meq/g. K.S.K. (Kosice) mines between 7,000 and 12,000 ktpy of clinoptilolite from a deposit at Bystra Nad Toplou.

Slovenia

Zeolites are mined and processed at Zaloska Gorica. The operation produces ground and micronized clinoptilolite for pozzolan and agricultural use.

Spain

Mordenite occurs in an Upper Miocene bentonite sequence near Cabo de Gata, about 14 km from Almeria. Montmorillonite is the major component of the bentonite, with mordenite the next most common mineral. Minas Volcan SA has capacity to mine 10 ktpy of zeolites from quarries in Almeria Province. Bentonitas Especiales SA mines and processes zeolites in Madrid Province in conjunction with its bentonite mining operations.

Turkey

There are several very large deposits of clinoptilolite in the central part of the Bigadic Basin. The largest deposit is reported to have an extensive reserve of 82% clinoptilolite. About 9,000 tpy are produced by Yapi Insaat ve Ticaret AS and Zeolitas Turizm Yapi Ticaret ve Sanayi AS (C. Turner, personal communication).

Ukraine

Several large clinoptilolite deposits are present in the Ukraine. The Sokimitsa deposit in the Transcarpathian Ukraine contains 60% clinoptilolite that has a cation-exchange capacity of 1.44 meq/g. The Zatisyansky Chemical plant at Zakarpaty produces about 15 ktpy of clinoptilolite.

TECHNOLOGY

Exploration Techniques

Most productive deposits occur in zeolitized vitroclastic tuffs or tuffaceous sediments of Tertiary or, to a much lesser extent, Mesozoic age. Though deposits in other geologic settings may be developed in the future, it is almost certain that bedded deposits will remain the principal source of natural zeolites.

Exploration for zeolite deposits is a challenge. When the Union Carbide exploration program began in 1958, no one had ever explored for zeolite deposits. In fact, almost no one except for company geologists knew where zeolite deposits occurred, much less what the outcrop of a zeolite deposit looked like.

Union Carbide used a simple but effective technique to locate the white to yellowish-white outcrops of zeolite deposits in the intermontane valleys of the western United States. Geologic maps of the Tertiary formations in the valleys were nonexistent. The geologists flew in light aircraft at an altitude of about 150 m above the terrain and posted the light-colored outcrops on 1:250,000 scale topographic maps. The outcrops were sampled, and if the sample adsorbed carbon dioxide in the portable field adsorption unit, the outcrop was extensively sampled and mapped. The samples were then sent to the Linde Company laboratory in Tonawanda, New York, for oxygen adsorption and XRD analysis.

The exploration program based on visual analysis from aircraft was effective. The program discovered every zeolite deposit now in production. Unfortunately, the Molecular Sieve Department of the Linde Company was interested only in chabazite, erionite, and mordenite—the zeolite minerals that adsorbed oxygen and could be used as adsorbents. Therefore, there was no interest in clinoptilolite, which is now the zeolite with the greatest commercial potential.

This kind of exploration program for zeolites would still work well in undeveloped areas without undertaking a costly grassroots exploration program. Zeolites are difficult to identify in the outcrop

because they are so finely crystalline they cannot be identified with a hand lens. Zeolites resemble fine-grained tuffaceous rocks, bentonite, diatomite, freshwater limestone, and fine-grained sediments. Nevertheless, with a little experience, zeolites can easily be identified in hand specimens, but XRD analysis is needed to identify the specific zeolite minerals.

One exploration technique is to examine and sample known zeolite occurrences and then examine adjacent areas for outcrops that appear to be similar in appearance. Many of the known zeolite deposits in the world, especially in North America and Europe, have not been sampled and characterized adequately, so there are many opportunities to develop new zeolite deposits without undertaking a costly exploration program.

As the uses and applications of natural zeolites are expanded, new and innovative exploration methods may be required to locate new sources. Exploration programs will be developed that identify exploration targets based on the geology of the region, known zeolite occurrences, and the desired characteristics of a deposit that might yield specific zeolite products.

Field exploration for zeolites depends on careful geologic examination and sampling. Zeolitized tuffs usually appear to be altered rocks, but locally may not be distinguishable from unaltered rocks. Outcrops of zeolitized tuffs are commonly yellowish-white to gray, massive and blocky, and generally resistant to weathering; they may also exhibit distinctive surface textures. Natural zeolites may contain iron oxides or other minerals that produce outcrops with various shades of red, brown, yellow, or green.

XRD analysis of outcrop and drill samples is the most effective technique available to identify zeolite minerals. Specific zeolite minerals or mixtures of minerals may be identified, and semiquantitative estimates can be made of their abundance. Ammonia CEC determination of samples is also a very effective early screening technique for zeolitized tuffs believed to contain clinoptilolite, chabazite, erionite, or phillipsite. This screens out heulandite and analcime, which have similar appearances but almost no commercial potential.

Samples of mordenite, chabazite, and erionite require XRD and adsorption or separation tests to determine their zeolite content. The least expensive method of determining the purity of a zeolite mineral is to measure its adsorption capacity for water vapor at the standard temperature 25°C (77°F) and 40% relative humidity. The sample is heated to about low red heat in a porcelain crucible, then cooled and weighed. It then is placed in a desiccator overnight at the standard temperature and humidity and weighed again. The weight gain is compared to the increase of weight of a standard sample of known purity of the same zeolite mineral.

Once a zeolite deposit is identified, it must be sampled, mapped, and drilled to determine its consistency in mineralogy and purity and its vertical and horizontal extent. With this information, the geologic and minable reserves can be calculated. The deposit must then be bulk sampled. These samples are used for pilot-plant testing and also to provide samples for customer acceptance of the suitability of the product for specific uses and applications. If all these are satisfactory and a market has been established, the deposit can be brought into production.

Mining Methods

Both bedded sedimentary and thick vitroclastic zeolite deposits are mined by surface methods. Conventional earth-moving equipment, including scrapers and loaders, are used to mine the zeolite bed. Selective mining and blending during removal or stockpiling controls any variations in the purity of the ores. Sampling drill holes, the area being mined, the haulage truck, and the process stream are all used for quality control.

Figure 6. EZ chabazite mine, Bowie, Arizona

Zeolites for special, high-value applications require selective open-pit mining. Dow Chemical Corporation, which now owns and operates the deposit in Bowie, Arizona, manufactures high-value molecular sieve and ion-exchange products mined from the 15-cm-thick chabazite bed (see Figure 6). Before mining, the deposit is drilled on 15.25-m or 7.62-m centers. Overburden is stripped from the bed with self-loading scrapers. All the overlying thin-bedded chabazite waste is scraped off with a road grader. The bed is then pulled up with a backhoe. Any clay adhering to the bottom of the chabazite is scraped off by hand.

The chabazite from each pit is stored in a separate stockpile. Chabazite is blended from the stockpiles to guarantee that every shipment contains no less than 85% chabazite. Each railroad car shipment is sampled. The samples are sent to the processing plant so that the chabazite content of the car is known prior to its arrival at the plant.

Mining at the Mud Hills clinoptilolite deposit in Southern California recovered ore with strict specifications in 30-cm slices from a 4.6-m-thick deposit to yield a very high value product for ion-exchange media used by BNFL.

Processing

Natural zeolites are crushed and screened into granules that range from coarse to fine. Some zeolites are micronized to products with a particle size of less than 5 μm . The granules are used in soil conditioners, aquarium filters, feed supplements, animal absorbents, or cat litter. Chabazite granules used in desiccant applications are double activated at 260°C (500°F) and shipped to the customer in sealed containers. The chabazite produced for adsorption applications is ground, mixed with a binder, extruded, and activated at 424°C (795°F) (see Figure 7).

Natural zeolites can be enhanced in performance by washing them with acid or NaCl (sodium chloride) solutions to raise the H^+ or Na^+ content, respectively. Clinoptilolite products are particularly enhanced in ion-exchange capacity by washing to replace the slower reacting K^+ ions with Na^+ ions. Thermal treatment of clinoptilolite slows calcium from blocking exchange sites (Eyde 2000).

Specifications

Specifications are based on the end use application of the zeolite product. The user almost always sets the specifications. The pro-

Figure 7. Zeolite processing plant at the Ash Meadows Deposit near the California-Nevada border

ducer must guarantee that the zeolite product will meet or exceed the user's specifications. A chabazite product used in a desiccant application would specify the weight percent of water adsorbed at a specific temperature and humidity. Clinoptilolite used in cation-ion exchange would have to exchange a specific amount of the ion being exchanged.

Natural zeolites must have a specification sheet that provides information on the chemical and physical properties of the product. The American Society for Testing and Materials (ASTM) Committee No. D-32 was established to set testing methods and standard specifications for zeolites in the United States. Unfortunately, the committee has not been successful in setting testing standards for natural zeolites.

Industrial mineral producers deal with specifications in two ways—either by selling products on a custom basis to the specifications negotiated with the buyer or selling them on a product-line basis where each product has a name or number designation and specific physical or chemical standards. In the United States and Europe, zeolite products are commonly sold under a trade name rather than a mineral name. Tables 3 and 4 are sample specification sheets for chabazite and clinoptilolite products.

Testing for Zeolite Mineral Identification

Natural zeolite minerals are identified primarily by their crystal habit. Chemical analyses alone are not a satisfactory method of identification because they all have similar chemical compositions. The same zeolite from different localities or even from different parts of the same deposit may not have exactly the same chemical composition. Macroscopic zeolites, particularly those occurring in vesicles and fractures in basaltic rocks, can be identified by careful visual examination. In virtually all the deposits being mined, the minerals are of microscopic grain size. Positive identification and semiquantitative determination of such fine-grained materials can be done only by laboratory methods. The principal methods of identification are XRD and scanning electron microscopy (SEM). Neither optical microscopy nor differential thermal analysis (DTA) is particularly useful for identifying zeolite minerals.

X-ray Diffraction

XRD is the most reliable and widely used method for identifying zeolite minerals and providing a semiquantitative estimate of the

Table 3. Chabazite* properties

Typical Properties	
Form	Powder or granules
Color	Light brown (dry brightness 43)
Ring members	8
Crystal size—chabazite	Less than 1 μm
Crystallinity	+90%
Density	1.73 g/cm ³
Pore size	4.1 \times 3.7 Å
Effective pore diameter	4.3 Å
Cavity size	11.0 \times 6.6 Å
Total pore volume	0.468 cm ³ /g
Surface area	520.95 m ² /g
Crystal void volume	0.47 cm ³ /cm ³
Packing density	Approximately 577 kg/m ³ (36 lb/ft ³)
SiO ₂ :Al ₂ O ₃ ratio	Approximately 4:1
Mohs hardness	4–5
Moisture as packaged	Less than 10% by weight
Stability	pH 3–12
Ion-exchange capacity	2.50 meq/g

Typical Chemical Analysis

percent present in the sample (Papke 1972). This method has a high degree of accuracy and can readily be used to identify individual minerals in mixtures of zeolite and nonzeolite minerals. A skilled technician is required to operate the XRD equipment, which may be automated and able to run multiple determinations unattended, and to interpret the results. XRD analysis is a non-destructive method, and the powder used for the analysis can be further tested. The method is least reliable in mixtures of minerals; the lower detection limit for an individual zeolite is about 1%. An experienced mineralogist is needed to interpret the diffraction trace. Papke (1972) and Slansky (1987) give more detailed descriptions of the XRD method.

Scanning Electron Microscopy

The scanning electron microscope is effective in identifying zeolite minerals and establishing their size, morphology, genesis, and mineralogic setting. Magnifications of several thousand times or more allow a visual examination of the zeolite minerals in small samples mounted on a specimen holder. Representative samples must be used to avoid misleading results. SEM analysis is relatively slow and costly.

Table 4. Clinoptilolite properties

Typical Properties*

Optical Microscopy

Optical microscopes are generally ineffective in identifying zeolite minerals in zeolitized tuffs because of the very small grain size of the zeolite minerals, their low birefringence, and variation of their indices of refraction with changes in chemical composition.

Differential Thermal Analysis

DTA can be used to identify zeolite minerals, but the method is not effective when several zeolites or certain other minerals are present or when only a small quantity of a mineral is available. Variations in the exchangeable-cation content may also cause differences in the differential thermal curve. The method is very useful in distinguishing clinoptilolite from the closely related mineral heulandite. Gottardi and Galli (1985) published a comprehensive collection of DTA curves for natural zeolites.

Other Methods

Other analytical methods can be used in special circumstances but they are generally complex, very costly, and not currently practical for exploration or quality control. Such methods include infrared

absorption spectrography, Mossbauer spectroscopy, electron spin resonance spectroscopy, electron spin echo spectrometry, solid-state nuclear magnetic resonance, neutron diffraction, and synchrotron XRD (Slansky 1987).

Testing for Characterization

In characterizing zeolitic materials for commercial uses, it is important to quantify other physical and chemical properties required by the specific application. The following are physical and chemical properties and tests that may typically be required: wet chemical analysis; CEC; specific gravity and bulk density; brightness, whiteness, and color; hydration/dehydration; gas adsorption; attrition in water; internal and external surface area; pore size; and volume.

By-products and Coproducts

Deposits containing two or more zeolites may yield several individual varietal products or mixtures of the zeolite minerals. For example, zeolite products from the Itaya mine in Japan, a clinoptilolite and mordenite deposit, include mordenite, clinoptilolite, and mixed mordenite-clinoptilolite products depending on the selectivity of mining and processing.

Zeolite mining may yield bentonite as a by-product or coproduct. Bentonite commonly occurs in the same geologic setting as natural zeolites. At the Teague Mineral Products operation in Oregon, both minerals are mined from nearby pits and processed in the same grinding plant.

USES

Agricultural Products

Zeolites are used as soil conditioners and fertilizer extenders, particularly in Japan, Cuba, and the former Soviet bloc countries in Eastern Europe. Zeolites increase the cation-exchange capacity, improve moisture retention, and, because of their high pH, buffer acidic soils. Zeolites act as a slow-release media for ammonia and to a lesser extent potassium. Zeolite soil conditioners preloaded with nitrogen are now available. The zeolite crystal structure shields the ammonium ion from rapid consumption by nitrifying bacteria (Ferguson 1984), allowing a reduction in the amount of nitrogen fertilizers applied to the soil. Chabazite and clinoptilolite are effective carriers of herbicides, pesticides, fungicides, enzymes, and bacteria because of their high ion-exchange and adsorption capacities.

Zeolite-polymer blends are being used to improve water retention in sandy soils. In fields watered by pivot irrigation systems, the production of corn increased by 30% and water consumption decreased by nearly an equivalent percentage (R. Salestrom, personal communication). A test plot on tailings from a large open-pit copper mine in Arizona was treated with a mixture of clinoptilolite-polymer blend and dry municipal sewer sludge. Native desert vegetation established itself on the test plot without being either seeded or irrigated (S.A. Bengston, personal communication).

Zeolites also act as scavengers for heavy-metal ions such as cadmium (Cd), copper (Cu), lead (Pb), and zinc (Zn) in soils, particularly those contaminated by industrial wastes. Clinoptilolite added to soils contaminated with strontium-90 and cesium-137 reduces the uptake of these radioisotopes by plants in areas contaminated by radioactive fallout, such as around the damaged Chernobyl reactor.

Animal Nutrition

Adding clinoptilolite to animal feeds in controlled amounts increases utilization of feed and decreases ammonia stress in animal digestive systems. Controlled feeding of clinoptilolite to chickens,

turkeys, and swine has increased growth rates, improved feed efficiency, reduced the incidence of diarrhea and related health problems, and produced a drier and less odoriferous excrement. Also, excrement and sewer sludge treated with zeolites are more effective fertilizers because their slow-release properties prevent fertilizer burns on the plants. The zeolite-treated manure is drier and less odoriferous than composted manure.

Feeding clinoptilolite, and to a lesser extent mordenite, to animals is an accepted practice in Japan, Cuba, Bulgaria, and Hungary (Griffiths 1987). The use is growing slowly and steadily in the United States and in Russia, but it is still not widely accepted (Pond 1993).

Clinoptilolite fed to broiler chickens in amounts of 1% to 3% of the total feed increases feed efficiency and lowers the time required to reach a marketable size. Laying chickens fed supplemental zeolite took fewer days to the first egg, had increased numbers of eggs, and had general improvement in health through a reduction in fecal bacteria (Griffiths 1987).

Clinoptilolite also reduces the incidence of post-weaning diarrhea when added to the starter diet of young pigs. A zeolite used as a feed supplement may also reduce the levels of antibiotics needed in feeds, particularly for swine.

Aquaculture

Zeolites are used in aquariums, fish farms, and fish hatcheries to avoid the buildup of ammonia to toxic levels. Fish hatcheries are using self-contained systems that recycle water to reduce downstream contamination from their effluent. Clinoptilolite is highly effective in the removal of ammonia from recirculating fish culture systems. In oxygen-poor environments, concentrations of less than 1 ppm ammonia can damage gill tissue, increase the incidence of gill disease, reduce the rate of growth, and increase mortality (Mumpton 1977).

In Alabama and Mississippi, clinoptilolite is being used to remove ammonia from catfish ponds (Williford, Reynolds, and Quiros 1991). Ammonia-removal kits containing granular clinoptilolite as the ion-exchange media are available in many pet supply stores for home aquarium use. The U.S. Fish and Wildlife Service has also successfully used clinoptilolite-charged systems for recirculating water in tank trucks transporting live fish.

Catalysis and Petroleum Refining

Zeolites with large channel sizes have large internal surface areas and can catalyze many types of reactions (Dwyer 1984). Though natural zeolites have been used in sorption applications in the petroleum and petrochemical industries, synthetic zeolites are generally used because of their larger channel sizes, greater adsorption capacities, and uniformity. Chabazite is used to remove water, carbon dioxide, and hydrogen sulfide from gaseous hydrocarbons, to remove HCl from gas streams, and to dry hydrogen and chlorine.

Desiccants

Activated chabazite is used as a carrier and desiccant in packaged enzymes and bacteria used to inoculate silage. Partially activated clinoptilolite and chabazite are used as anticaking agents in cattle feeds containing mineral and organic supplements and other bulk agricultural and chemical products shipped in pneumatic containers. Small amounts of zeolite desiccant are blended with animal feed, fertilizers, and hygroscopic chemicals before sealing the products into bags.

Dimension Stone

Zeolitic tuffs have been used for thousands of years as lightweight, durable dimension stone. The physical properties of such stone are

important. Zeolitic tuffs have low bulk densities, are weather resistant, have superior insulating properties, and can be easily cut into attractive stone.

Many buildings in ancient and modern Rome and Naples have been constructed from local zeolite sources, particularly from the Neapolitan Yellow Tuff (Aie llo 1993). In central Europe, many buildings and cathedrals were constructed with blocks of zeolitic tuff. Quarries in the Laacher See Area in Germany, Kurdzali in Bulgaria, and Tokaj in Hungary produced blocks of zeolitic tuff for dimension stone used in building construction.

Several sources in Japan have produced zeolitic dimension stone for centuries, particularly from pumiceous marine tuffs in the Green Tuff region, Tochigi Prefecture. The principal source is a quarry near Otsunomiya City, where a green tuff bed 108 m thick has been mined for hundreds of years (Mumpton 1978).

In the United States, the use of zeolitic tuff dimension stone has been limited to a few areas in Nevada and Oregon, where several structures were constructed from blocks of zeolitic tuff from local quarries. The old Nye County courthouse, St. Patrick's Catholic Church, and several commercial buildings in Tonopah, Nevada, were built with blocks of zeolitic tuff.

Gas Separation

Zeolites are used to separate nitrogen and oxygen to produce a gas stream containing up to 95% oxygen. Mordenite appears to be the best natural zeolite for oxygen generation, although clinoptilolite and chabazite have also been used; pressure swing adsorption (PSA) plants using synthetic zeolites have displaced the compression-expansion air-separation systems.

PSA plants that use mordenite were designed and used principally in Japan to supply oxygen for basic oxygen furnaces in steel mills. PSA plants supply oxygen to municipal wastewater treatment plants, hospitals, and other users. Perhaps the most important application is the small oxygen generators used in homes to provide continuous oxygen to patients with pulmonary diseases. Natural zeolites have been displaced in virtually all the industrial and medical applications by synthetic zeolites, which have significantly higher adsorption capacities than natural mordenite.

Ion-Exchange Applications

The ability to exchange cations is one of the most important properties of zeolites. Cation-exchange capacity is a measure of the number of cations per unit weight available for exchange, usually expressed as milli equivalents per gram or milli equivalents per 100 grams of zeolite. The ammonia ion is most commonly used for CEC testing. The result is referred to as the ammonia ion-exchange capacity.

Both chabazite and clinoptilolite are used to treat mine water and metallurgical effluents. Because chabazite has a higher selectivity for thallium than any other natural zeolite or ion-exchange resin, it is used to remove thallium from mine water. Sodium chabazite modified with ferrous iron removes arsenic from solution without first converting it to arsenate (Eyde 2000). The ZELFLON technology uses clinoptilolite to treat municipal sewage (Eyde 2000).

NSF International approved clinoptilolite for use in swimming-pool filtration systems. In these systems, granular clinoptilolite replaces the sand in the filter. Clinoptilolite is superior to sand because it removes chloramines, heavy metals, urea, and organic matter from the pool water.

Synthetic zeolites are used in detergents. This is because natural zeolites are not uniform in purity and composition; are inferior in color, brightness, and CEC; and have smaller channel sizes and higher percentage of iron and other impurities. Natural zeolites are superior to synthetic ones for uses such as the treatment of radio-

active waste or the removal of metals from low-pH solutions because of their hardness and resistance to attrition and degradation by intense radiation.

Fine grinding of zeolitic materials can improve their CEC by increasing their surface area, especially when the zeolite (usually mordenite) has a low permeability. Zeolite minerals with high CEC include clinoptilolite, erionite philipsite, chabazite, and mordenite. Minerals with low CEC include heulandite, laumontite, and analcime.

Medical and Personal Care Applications

The U.S. armed forces uses zeolite products that stop bleeding from wounds by promoting clotting (Healy 2003). Clinoptilolite has been used successfully as a polishing agent in fluoride-containing toothpaste by allowing a higher level of fluoride to remain in anionic form (Kato et al. 1970). Clinoptilolite is encased in tampons to control odor and reduce the incidence of sepsis. Because of its ability to absorb ammonia ions from air and water, clinoptilolite has been used in products such as baby powder and filler in disposable baby diapers, and as an ammonia control product in diaper pails.

Natural Gas Purification

Chabazite has been used to separate carbon dioxide, hydrogen sulfide, and other gases from methane produced from natural gas and oil wells (Mumpton 1978). Other sources of methane that use either synthetic or natural zeolites to remove noncombustible gases and contaminants include municipal wastewater treatment plants, sanitary landfills, and animal waste treatment facilities. NRG Corporation constructed two gas treatment plants in the Los Angeles, California, area that used the NuFuel PSA process to produce pipeline quality methane. The Palos Verdes Landfill plant treated gas containing about 50% methane and 40% carbon dioxide to produce about 30,000 m³ of methane per day. The other NRG Corporation plant treated casing head gas at the Farmers Market oil field. Both plants used activated extrudates produced from chabazite mined at the Bowie, Arizona, deposit (Anon. 1975).

Nuclear Waste Treatment and Handling

Chabazite and clinoptilolite are used in the treatment, handling, and containment in engineering structures for the storage of nuclear wastes (Grant, Skriba, and Saha 1987; Grant et al. 1988, 1989). Natural zeolites have the unique ability to selectively remove Sr⁹⁰, Cs¹³⁷, and other dangerous isotopes from solutions containing high concentrations of competing ions. Natural zeolites are less expensive than organic ion-exchange resins and much more resistant to degradation from radiation. Zeolites melt at low temperature into a stable silicate glass, which greatly reduces the volume of the radioactive waste. By encapsulating the radioactive glass in concrete, the radioactive cations can be safely stored in a secure disposal site.

The Hanford Laboratories of Battelle Pacific Northwest Laboratory in Richland, Washington, initially demonstrated the high efficiency of clinoptilolite from Hector, California, in removing radioactive Cs¹³⁷ and Sr⁹⁰ from low-level waste streams at nuclear facilities. Radioactive solution treatment at Hanford has processed millions of gallons of solutions. A comparable Sr⁹⁰/Cs¹³⁷ waste treatment is used at the National Reactor Testing Station at Arco, Idaho; West Valley, New York; and other nuclear facilities. Chabazite products IE-95 and IE-96 from the Bowie deposit were used in the cleanup of the Three Mile Island nuclear power plant site (King and Opelka 1982; Bostick and Guo 1996).

Ion-exchange treatment utilizing clinoptilolite has also been used for nuclear-waste treatment in other countries, including Russia, Ukraine, Japan, Hungary, Bulgaria, Canada, Italy, the United

Kingdom, France, and Germany. Large tonnages of clinoptilolite were used in direct application to contaminated soils at the devastated Chernobyl nuclear power plant to contain radioactive contaminants spilled during the accident (Griffiths 1987; Chelishchev 1993).

Mixed clinoptilolite and mordenite have been used for Cs¹³⁷ removal in Japan (Kato 1974). Clinoptilolite from the Tokaj District in Hungary has been used to encapsulate Sr⁹⁰ for solid waste disposal and removal of Sr⁹⁰ and Cs¹³⁷ from effluent waste streams (Adam, Kakasy, and Pallos 1971). In Canada, clinoptilolite was used to recover Sr⁹⁰ and Cs¹³⁷ from waste solutions in underground disposal sites at Chalk Run, Ontario (Mathers and Watson 1962).

Chabazite and phillipsite from the Neapolitan Yellow Tuff at Naples, Italy, have been used to remove Cs¹³⁷ and Sr⁹⁰ from nuclear effluents. The zeolite minerals loaded with the radioactive cesium and strontium were stored in secure underground disposal sites at Cassacig, Italy (Anon. 1972).

BNFL uses clinoptilolite from the Mud Hills deposit near Barstow, California, to selectively exchange Sr⁹⁰, Cs¹³⁷, and other radioisotopes from effluent waste streams at its nuclear fuel reprocessing plant at Sellafield, U.K. (Anon. 1990). Levels of Sr⁹⁰ and Cs¹³⁷ in the clinoptilolite-treated plant effluent, which is discharged into the Irish Sea, have dropped to very low levels.

Battelle Pacific Northwest Laboratory uses clinoptilolite in engineered sorbent barriers in containment and waste storage structures for low-level nuclear wastes (Freeman and Jones 1989).

Odor Control

Natural zeolites, particularly clinoptilolite, adsorb ammonia ions. This process suppresses odors from fecal matter and urine. Hydrated zeolites adsorb ammonia vapor; when the gas enters the zeolite pores, it bonds to or replaces crystalline water (Frederickson 1987).

In Europe and the United States, clinoptilolite is used as a pet litter and to suppress odors in horse stalls (Eyde 1987). In Japan, clinoptilolite and mordenite are used to control odors from poultry and swine. Crushed and sized zeolites, principally clinoptilolite, have proven effective in controlling the pungent odor of ammonia fumes produced when animal excrement dries (Griffiths 1987). Granular clinoptilolite is applied directly to the floors in pens and stables and in litter trays for cats and small pets. Adding clinoptilolite as a supplement to animal feeds has a nutritional benefit in addition to reducing the odor from fecal matter and urine.

Natural zeolites, notably clinoptilolite, chabazite, and phillipsite, have also been used for odor control in personal products (e.g., in athletic shoes). Room air cleaners with zeolite filters have also been used in living quarters and to remove high-ammonia urine odors in nursing homes and similar facilities. Ground clinoptilolite is effective as a dry carpet cleaner, particularly to remove pet odors.

Paper Fillers

Natural zeolites have been used as fillers in some specialty paper products. Clinoptilolite and the crystalline quartz that occurs as an impurity in the zeolitic tuffs are abrasive. In addition, clinoptilolite has a low brightness and a poor color (Kobayashi 1970). Clinoptilolite is not competitive with kaolin and calcium carbonate for either coating or filling most paper products.

Pozzolan and Cement

Pozzolan is a naturally occurring cementaceous material that can replace up to 25% of the portland cement in concrete. Pozzolans both improve the quality and reduce the cost of concrete. Zeolitic tuffs have been used as pozzolan in many places in the world. The Romans employed pozzolanic materials in aqueducts, public buildings, and high ways using the Neapolitan Yellow Tuff near Poz-

zuoli, Italy. In Europe, zeolites are being mined in Serbia, Germany, Bulgaria, and other countries for use as pozzolan. The minerals used include clinoptilolite, natrolite, skolezite, and phillipsite.

Monolith Portland Cement Company mined zeolitic ash-flow tuffs near Tehachapi, California, for pozzolan in cement. The use of pozzolanic cements in the construction of the 400-km-long Los Angeles aqueduct in 1912 saved several million dollars by enabling a 25% reduction in the amount of cement consumed.

GSA Resources and C2C Corporation developed a lightweight, oil-well cement additive that Halliburton Energy Services is evaluating. The additive is based on the chabazite in the thin-bedded horizon that overlies the high-purity ore bed at the Bowie Arizona, deposit. The additive is blended with the portland Class G cement to optimize placement within a well bore. The technology is based on research done at the Institute of Architecture, Slovak Academy of Sciences (Janotka, Krajč, and Dzivák 2003).

Sewage Treatment

Clinoptilolite and chabazite remove ammonia and some heavy metals from sewage and other effluent streams. The ammonia removed can be discharged into the atmosphere, recovered as a gas by-product, or converted to an ammonium sulfate fertilizer. Plants in Truckee, California; Rosemont, Minnesota; and Manassas, Virginia, have operated successfully for many years using clinoptilolite in tertiary sewage treatment processes to remove ammonia.

Zeolite Australia licensed the ZELfloc technology that uses zeolites for municipal wastewater treatment. The company has 14 wastewater treatment plants using the technology (Eyde 2000). Supersorb, another Australian company, has undertaken full-scale trials of an activated zeolite technology at the Water Corporation of Western Australia Kwinana Wastewater Treatment Plant in Queensland (Crossley 2000).

An improved environment is the incentive behind the increased use of zeolites in tertiary wastewater treatment. Ammonia ions should be removed because they are toxic to fish and other aquatic life and contribute to rapid growth of algae and the eutrophication of streams and lakes.

Solar Energy and Heat Exchange

Chabazite and clinoptilolite absorb and release heat from solar radiation for air conditioning, refrigeration, and water heating applications. The dehydration of the zeolite during the day and its rehydration at night result in the exchange of several hundred BTUs per kilogram of zeolite, sufficient to operate refrigerators or to cool small buildings (Tchernev 1993). The study estimated that 1 t of zeolite in solar panels spread over 19 m² of roof surface will produce 1 t of air conditioning. Recreational uses such as in beverage coolers, and use in less developed countries where power is not available to refrigerate medical supplies and food, are important applications.

Stack Gas Cleanup

Natural zeolites can be used to remove sulfur dioxide from the stack gases of coal-burning power plants. Clinoptilolite and mordenite can adsorb as much as 200 mg of SO₂ (sulfur dioxide) per gram of zeolite under static conditions and as much as 40 mg under dynamic conditions, even in the presence of high percentages of carbon dioxide. These zeolites are especially suited to the low-pH and high-temperature conditions of exhaust gas systems.

ECONOMIC FACTORS

Markets

Synthetic zeolites were produced and used for many years before Union Carbide discovered large deposits of chabazite, clinoptilolite,

erionite, and mordenite. In fact, their Linde Company subsidiary that developed and sold the first 5A molecular sieve products marketed the Bowie chabazite as their AW500 synthetic zeolite product in 1961. AW500 was sold into applications where the adsorption bed was exposed to an acidic environment in which the 5A synthetic molecular sieve quickly deteriorated.

Union Carbide was not interested in the mineral clinoptilolite because at that time it had no adsorption applications. Had the company been interested in clinoptilolite, it could have acquired all of the major deposits in the western United States. Although W.R. Grace and Company acquired the eastern part of the Bowie chabazite deposit in 1965, no major mining or oil companies acquired large zeolite reserves until they entered the natural zeolite business about 10 years later.

Natural zeolites are still an undeveloped facet of the zeolite business. Synthetic zeolite sales worldwide total several billion dollars, whereas natural zeolite sales are only a few million dollars. No formal commodity markets exist, and sales for lower value products are confined mostly to countries with zeolite resources. Higher value products may be sold internationally, but their total value worldwide is still small. Synthetic zeolites have established major, growing markets through silicate chemical manufacturers, mostly in North America, Western Europe, and Japan.

Because of their very wide range of applications, natural zeolites sell into diverse markets. Japan has a particularly wide range of zeolite markets for agricultural, industrial, and consumer uses. North American sales are principally for agricultural, ion-exchange, and pet litter applications. Markets in Western Europe, the former Eastern bloc countries, and Cuba are primarily for agricultural products, with a growing industrial market sector.

The fastest growing market sector is for ion-exchange applications. Clinoptilolite is a superior swimming pool filtration product that will displace sand as the preferred media. The new tertiary wastewater treatment systems will experience continuing strong growth.

Steady growth is anticipated for agricultural, industrial, and consumer applications. The strongest areas of market growth in North America are expected to be in water treatment, deodorants, pet litter, soil treatment, and nuclear waste treatment and containment.

Values and Costs

The cost of zeolite products depends on the type and degree of processing that must be done to satisfy targeted market specifications. Mining costs are generally fairly low, typically \$3 to \$6/t, unless very selective mining is done.

Most natural zeolites are sold into low-value industrial or agricultural markets, commonly selling for \$30 to \$70/t for granular products down to 40 mesh, and \$50 to \$120/t for ground materials in a range of -40 to -325 mesh. Consumer products such as pet litter, fish-tank media, or deodorant materials commonly sell for \$0.50 to \$4.50/kg at the retail level.

Products for specialty industrial applications, such as radioactive waste filtration media, specialty adsorbents, and surface modified products, are sold for several dollars per kilogram or thousands of dollars per ton. Specialty materials with products developed for specific markets are highly profitable even though the market for these products may be very limited.

Transportation

Zeolite products are generally transported by highway or rail carriers in bulk, in 1-t "supersacks," or in multiwall paper bags, usually

palletized. The products are not hazardous and present no special problems, subject to proper labeling and handling. Chabazite and clinoptilolite, which have been stored at high temperatures or low humidity, can adsorb several weight-percent water if their destination has a high humidity. Zeolites prepared as dimension stone are shipped as any other stone products, generally palletized and by truck.

Transportation costs strongly affect the distance a lower-value zeolite can be hauled to reach markets. Agricultural-grade clinoptilolite from the western United States can reach markets in the eastern half of the country.

Future imports from Greece, Italy, China, and other tidewater sources with low ocean freight rates could make some materials produced in the western United States uncompetitive. High-value-added zeolites can generally be shipped nationwide and even to international destinations because the freight is such a small incremental cost in relation to the cost of the product.

Alternate Materials

Natural zeolites are competitive on the basis of price and performance with other mineral products. It is difficult for a new product to displace one with performance characteristics that are known and are satisfactory to the user. There are many established alternate materials for most zeolite applications. Market entry of a natural zeolite product requires equivalent or superior performance or a significant cost advantage over the product being used.

Synthetic zeolites (molecular sieves) are natural zeolites' principal competitor. Synthetic zeolites often can be modified in physical and chemical properties to enhance their performance in specific applications. The synthetics are more uniform in quality than their natural equivalents. Natural zeolites have an advantage over synthetic materials in some applications (e.g., cesium and strontium adsorption in radioactive waste cleanup) and are also able to function at lower pH levels. They are also generally less expensive than synthetic zeolite products, which gives them a superior price performance ratio.

Activated carbon, synthetic ion-exchange resins, and similar materials can be more effective than zeolites for many ion-exchange applications. Activated bentonite, silica gel, calcium oxide, calcined gypsum, and other minerals also can be competitive adsorbents and desiccants in a comparative price range.

GOVERNMENTAL CONSIDERATIONS

Taxes, Subsidies, and Depletion Allowance

No specific taxes are related to zeolites, and the material is not subject to any government subsidies in the United States and Canada. The depletion allowance is 14% for natural zeolites mined in the United States.

Zoning and Land Use

Natural zeolite deposits experience zoning and land use restrictions similar to most other fine-grained minerals such as kaolin or diatomite. Most zeolite deposits are located in rural areas, so their utilization seldom interferes with urban development. The very large zeolite deposits around Naples, Italy, are a conspicuous exception, but the deposits are so extensive that many other sites in the region are available where disturbing residential or industrial lands is not an issue.

Environmental Regulations

Environmental regulations are always a matter of concern. Excessive regulation is always a source of conflict between government

regulators and mine operators. Natural zeolite mines and processing facilities generally present no serious environmental problems, with two possible exceptions:

1. Erionite and mordenite may be fibrous. Fibrous erionite is a Class 1 carcinogen. Mordenite is not known to be a carcinogen.
2. Crystalline silica commonly occurs in zeolite deposits, and the finely ground products may contain more than 0.1% respirable silica.

Natural zeolites are dusty materials when crushed and ground. Therefore, air quality standards should be maintained carefully during mining and processing.

Fugitive dust from mining and plant facilities may be considered a local environmental pollutant. Most zeolite deposits contain silica minerals in the form of amorphous silica such as opal or opal-CT, cristobalite, or crystalline silica. Processing plants therefore must have air-pollution control systems ranging from standard bag-house dust collectors to electrolytic precipitators to minimize worker exposure to fugitive dust at grinding mills or bagging stations and to comply with local air quality control requirements. Most zeolite production uses dry processing methods.

Zeolite processing will inevitably use water-washing and wet classification methods, requiring proper handling of plant effluent and tailings pond discharges. Zeolite minerals are generally considered to be chemically inert, and most are nonfibrous. Erionite is classified as a fibrous, acicular mineral and has been labeled a human carcinogen on the basis of medical studies of the large number of mesothelioma cases in the Cadocchia District of Turkey. Mordenite is also a fibrous mineral but is currently not regarded as a potential carcinogen.

FUTURE TRENDS AND PROBLEMS

Future Trends

The zeolite industry continues to develop new applications in both industrial and consumer markets. Most of this activity and growth, however, has been in synthetic zeolites. Most natural zeolites uses are in commodity and lower-value applications such as agriculture or pozzolan. This is changing. Specialty and consumer applications are the fastest growing segments of the natural zeolite market.

Chabazite and clinoptilolite are the only ion-exchange products that do not degrade when exposed to radiation. The zeolites used to clean up radioactive waste streams sell from \$2/kg to as much as \$14/kg. Clinoptilolite is displacing sand as a filtration media in swimming pool filters. These are applications where the physical and chemical properties of natural zeolites are superior to synthetic zeolites or other ion-exchange media.

Although the production of natural zeolites in North America is growing slowly, the value of this production is increasing more rapidly. This has occurred because of the shift from commodity to specialty and performance products. This trend will continue as more specialty products such as clinoptilolite coated with the quaternary amine hexadecyltrimethyl-ammonium are developed. (Bowman 2003). These organophilic zeolite products are now available for removing organic chemicals from ground- and surface waters. The coated zeolite products do not swell in water and therefore can displace organoclay products that swell and block circulation.

The producers of natural zeolite have characterized their products and provide specification sheets that document the physical and chemical properties. Still, no high-purity-beneficiated zeolite products are available. The technology is available to beneficiate zeolites by air separation, wet processing, or flotation. Until beneficiated clinoptilolite products become available as powders, beads,

or extrudates, natural zeolite products will be unable to gain access to many high-value-added specialty and performance uses and applications.

The highest purity zeolite product available in North America is the chabazite from the Bowie, Arizona, deposit. This unique deposit was formed when airborne volcanic ash from a distant volcanic eruption was deposited in a saline alkaline lake. By the time the ash arrived at the lake, virtually all the other minerals had been removed by natural air separation and only the glass fraction remained.

Problems

The use of inclusive generic mineral names for both the fibrous and nonfibrous varieties of erionite, phillipsite, and mordenite is inaccurate and has resulted in the designation of the nonfibrous varieties of these minerals as carcinogens. Nonfibrous erionite, phillipsite, and mordenite were identified in samples being studied for the U.S. Bureau of Mines report on size and shape characterization of fibrous zeolites by electron microscopy (Shedd, Virta, and Wylie 1982). The erionite in the Bowie deposit was judged to be nonfibrous. Yet the *Sixth Annual Report on Carcinogens* classifies all erionite as fibrous and as a carcinogen (Eyre 1996).

Because erionite has been classified as a carcinogen, it cannot be used in consumer products. The presence of even trace amounts of erionite may prevent its use or consideration for some applications. Mordenite has also been designated as a fibrous mineral but has not been classified as a carcinogen. Figures 8 and 9 illustrate the differences in the crystal morphology between fibrous and nonfibrous erionite (Eyre 1996). Natural zeolites usually contain some crystalline silica, which must be listed on the Material Safety Data Sheet.

ACKNOWLEDGMENTS

The zeolite chapter in the 6th edition of *Industrial Minerals and Rocks* was a carefully researched and referenced chapter that accurately summarized the content of the four outstanding individual papers in the 5th edition. This chapter has relied heavily in places on the data in the 6th edition (Holmes 1994), using some sections with no or very little change. The goal in the 7th edition is to update the previous chapters and to place more emphasis on the productive deposits and the end-use applications of the zeolites being produced. As a result, the bibliography has been updated and significantly reduced in size, a difficult task because each reference is important, and any of the references could be the inspiration for the development of a world-class natural zeolite product.

Zirconium and Hafnium

Philip Murphy and Louise Frick

INTRODUCTION

Elemental zirconium (Zr) was first identified and named in 1789 by the German chemist M.H. Klaproth, who called it zirconium after the Arabic word *zarquán*, meaning gold colored. It is the 20th most abundant element in terrestrial rocks, making up 0.016% of the earth's crust. The metal was first isolated in 1824 by the Swedish chemist J.J. Berzelius, but it was another 100 years before A.E. von Arkel first processed pure zirconium in 1925. Hafnium (Hf) is so chemically similar to zirconium that it was not discovered until 1923, when D. Coster and A.K. von Hevesy detected it using x-ray spectrographic analysis.

Zirconium and hafnium occur most commonly in nature as the mineral zircon (ZrSiO_4) and less commonly as baddeleyite (ZrO_2). They are also found as a variety of other silicates. Zircon was identified as a component in alluvial and beach sands in 1895, but it was not produced in any quantity until 20 years later. During World War I, it was produced as a coproduct of beach sand mining for titanium minerals just south of Jacksonville Beach, Florida, and was patented as a refractory. It was not until the 1930s, when Zircon Rutile Ltd. began mining at Byron Bay on the east coast of Australia, that zircon was first used as foundry sand. Later in the 1940s, NL Industries and Humphreys Gold Corp. began production of zircon sands from fossil beaches in northeast Florida. Baddeleyite first became available as a commercial product in 1916, but never in comparable quantities to zircon.

MINERALOGY AND GEOLOGY

Zirconium and Hafnium Chemistry

Zirconium is a transition element with the atomic number 40. It occurs together with titanium and hafnium in Group IV of the periodic table. The similarity in the electron structure of these elements is the reason that all three have similar chemical and physical properties and invariably occur together in nature.

Zirconium forms the dioxide, zirconia (ZrO_2), along with two other oxides of lower oxidation states. It reacts with hydroxides and carbonates to form zirconates (e.g., Na_2ZrO_3). Adding alkali to zirconium salt results in the formation of zirconium hydroxide, which is readily soluble in acids. In nature, zirconium occurs most commonly as the silicate mineral ZrSiO_4 and less commonly as the dioxide ZrO_2 . It also occurs in at least 20 other minerals, either as an oxide or a silicate.

Table 1. Key properties of zircon and baddeleyite

Property	Zircon	Baddeleyite
Formula	ZrSiO_4	ZrO_2
Specific gravity	4.68	5.5–6.0
Hardness (Mohs scale)	7.5	6.5
Refractive index ω	1.923–1.960	2.13–2.20
Refractive index ϵ	1.968–2.015	
Melting point	2,200°C	
Thermal conductivity	$2.1 \text{ W m}^{-1} \text{ C}^{-1}$	
Thermal expansion	$2.5 \times 10^{-6} \text{ C}^{-1}$	
Specific heat	$550 \text{ J kg}^{-1} \text{ C}^{-1}$	
Bulk density	2,600–2,900 kg m^{-3}	5.74

Separating hafnium from zirconium is extremely difficult because of their similar chemical and physical properties, and chemical analyses of zirconium minerals for commercial applications are virtually always based on the zirconia + hafnia ($\text{ZrO}_2 + \text{HfO}_2$) content, often simply abbreviated to ZrO_2 .

Physical Properties of Zircon

Zircon is an extremely refractory mineral with a high melting point, a low and regular coefficient of thermal expansion, and high thermal conductivity (Table 1). These properties are responsible for zircon's effective performance as a refractory material and as a foundry sand. The mineral has a high hardness and is thus resistant to abrasion.

Highly crystalline zircon does not absorb or reflect any particular wavelength of visible light. Combined with its high refractive index, this allows zircon to scatter all wavelengths of light when milled to a size similar to the wavelength of visible light (0.4–0.7 μm). This unique property allows zircon to be used as an opacifier in ceramic applications. By scattering all wavelengths of visible light, the zircon makes ceramic surfaces appear white.

The effectiveness of zircon in this function is influenced by its crystallinity and chemistry. Impurities such as uranium (U), thorium (Th), and yttrium (Y) can distort the zircon crystal structure creating point defects. Similarly, radioactive decay of uranium and thorium in the zircon also distorts the zircon structure. In extreme

cases, this can result in part or all of the zircon crystal becoming amorphous, producing what is known as metamict zircon.

Geology of Zircon and Baddeleyite

Zircon is a common accessory mineral in granitic rocks and pegmatites. It is one of the earliest minerals to crystallize from a cooling magma and sometimes incorporates inclusions. Much of the zircon in these rocks crystallizes in tetragonal prisms with pyramidal terminations; however, it also commonly occurs as rounded grains in igneous rocks. It is sometimes found in metamorphic rocks such as gneiss and schists. Because it is resistant to mechanical and chemical disintegration, it appears as a detrital mineral in river and beach sands. Zircon can also occur as a gemstone and has been recognized as a semiprecious stone since biblical times.

Although zircon is a common accessory mineral, it is rarely found in high concentrations in anything other than sedimentary deposits, where it has been concentrated over time by the processes of erosion and deposited along with other heavy minerals (HM) such as ilmenite, rutile, monazite, garnet, staurolite, and kyanite. Most commercial sedimentary deposits of titanium minerals and zircon are found on Quaternary age shorelines (0 to 2 million years) on the trailing margins of continents. They include beach, or strand line, deposits and coastal Aeolian dunes.

The geology of baddeleyite deposits is very different from that of zircon deposits. Baddeleyite has recently been mined alongside a wide range of mineral products from two large, ultrabasic, geologically complex deposits. The operation in the Kovdor Complex in Russia still mines baddeleyite, but falling grades at the Phalaborwa Complex in South Africa have put an end to baddeleyite production.

A commercial supply of zirconia from the rock caldesite has been investigated in the United States, and eudialyte is of minor commercial importance.

GLOBAL OCCURRENCE OF ZIRCON AND BADDELEYITE

Commercial zircon deposits occur almost exclusively in four countries: Australia, South Africa, the United States, and India. These tend to comprise coastal Quaternary-age sedimentary deposits, but also a small number of older, highly altered, mineralogically complex deposits are often found many hundreds of kilometers from the present coastline.

Australia

Australia has been the world's principal source of zircon since production of mineral sands first started on the east coast of the country, between Broken Bay, New South Wales, and Rockhampton, Queensland. Production from this region has declined considerably, however, because of depletion of resources and environmental constraints, and the only remaining significant source is the deposits on North Stradbroke Island in Queensland.

On Australia's west coast, the Eneabba region has been the world's most important source of zircon since the late 1970s, but production from this area is now declining because of lower grades and depleted resources. Zircon also occurs south of Perth, around Bunbury and Capel, but here the HM suite is less rich in zircon than it is at Eneabba.

The Murray Basin in inland southeastern Australia is host to substantial HM sand mineralization. Many of the projects being evaluated in the region are high in rutile and zircon, and although a number of these have been known for many years, the complexity of the mineral assemblage, together with the fine grain size of the zircon and elevated levels of uranium and thorium, has so far constrained their development.

The Eucla Basin, located onshore from the Great Australian Bight, seems likely to become Australia's newest mineral sands province. Toward the end of 2004, Iluka Resources Limited announced two discoveries on the eastern margin of the basin, which suggest that the region is highly prospective for mineral sands mineralization. The mineralization that has been found to date is particularly rich in zircon, and may well prove to be comparable to the Eneabba region of Western Australia.

Africa

South Africa hosts the largest known deposits of zircon in Africa. On the east coast, the Richards Bay Minerals deposit is one of the world's largest sources of zircon. Other deposits exist along that coastline, one of which is being mined by Ticon South Africa. Farther north along the same coastline, in Mozambique, are three very large, as yet undeveloped, titanium resources that contain some associated zircon.

On the west coast of South Africa, Namakwa Sands mines zircon deposits between Standfontein and Oranjemond.

United States

The two centers of zircon mining in the United States are the Jacksonville District, which spans Florida and Georgia and includes the Trail Ridge deposit and the Green Cove Springs deposit, and the Old Hickory deposit in Virginia.

India

Because the zircon content in deposits currently mined in India is relatively low, the country is not a significant producer of zircon. Deposits in Tamil Nadu, which are currently the subject of potential development proposals, have higher zircon to titania (TiO_2) ratios and could ultimately become a new source of supply.

WORLD RESERVES

The U.S. Geological Survey (USGS) provides the only published source of zircon reserve data, and Table 2 gives the latest published estimates. Identified world resources of zircon exceed 70 Mt.

Resources of hafnium in the United States are estimated to be about 130,000 t, a available in the 14-Mt domestic resources of zircon. World resources of hafnium are associated with those of zircon and baddeleyite and exceed 1 Mt.

According to these estimates, South Africa and Australia have the largest reserves of zircon and are also the largest commercial producers. The United States has moderate reserves of zircon and is the world's third largest producer. Other important occurrences are in Brazil, India, and Ukraine.

EXPLORATION AND EVALUATION

Exploration

Zircon exploration techniques are the same as those for titanium minerals, because both occur in the same deposits. Most commonly, target areas are selected where large volumes of sand are present and where beach ridges and other features associated with shorelines are known to occur. Early explorers used USGS quadrangle maps, physiographic references, aerial photographs, and often word of mouth to find target areas. Modern methods have become much more refined since the advent of Earth Resource Technology Satellite (ERTS) imagery, manned space flight photography, and new developments in computer science. In some cases, such as at Eneabba, farmers have discovered deposits on their land.

A Geiger counter or scintillometer can be useful in detecting HM deposits where radioactive monazite is present. Although geophysical methods such as magnetometer survey and induced

Table 2. World reserves of zirconium and hafnium

	Zirconium Mine Production, kt		Zirconium		Hafnium	
	2002	2003	Reserves	Reserve Base	Reserves	Reserve Base
			ZrO ₂ , Mt		HfO ₂ , kt	
Australia 408		400	9.1	30	180	600
Brazil	21	30	2.2	4.6	44	91
China	15	15	0.5	3.7	na*	na

* na = not available.

polarization have been tested, they are not widely used in HM prospecting.

A variety of drilling systems are available for beach sand exploration: hand auger, vehicle-mounted power auger, and reverse-circulation drills using both water and air to force the mineral to the surface. Each has its advantage, and one is chosen because it is thought to be the best for a particular type of deposit.

Evaluation of a Deposit

Gold pans of various sizes and materials of construction as well as vanning plaques can be used in the field to estimate the percentage of HM present in a sand. Evaluating prospect samples and ores in the laboratory usually requires separating the HM as a first step. The conventional methods use heavy liquids (tetrabromoethane, bromoform, methylene iodide, or Clerichi solutions). The heavy liquids are toxic, so some risk is involved in their use, and this has caused them to be banned in some countries (e.g., England). Newly invented nontoxic tung state solutions that use water instead of organic solvents are considered to be much safer than the conventional heavy liquids. Another new development in HM separation equipment is the Magstream separator, which separates HM by specific gravity using a nontoxic ferro-solution rotating in a magnetic field. The specific gravity is set by adjusting the rotational speed of the separation tube. In addition to gravity separations, the Magstream can also make magnetic separations. It is a very useful tool in HM evaluations because it can be used to concentrate zircon and the other HM for both chemical analysis and physical testing.

Analytical Methods

For many years, wet analytical chemistry methods were used to analyze zirconium-bearing materials. This type of analysis is very difficult because zircon is inert and can be taken into solution only with fusion methods with a strong flux. Because zirconium and hafnium have almost identical chemical properties, wet chemical methods cannot be used routinely to determine composition by individual element. Instead, wet analyses report combined ZrO₂ and HfO₂ as 67.2% ZrO₂ for pure zircon. In the past 20 years, x-ray fluorescence (XRF) has replaced chemical methods of analysis almost entirely.

For many years, grain counting (point counting) was a popular and useful means of identifying minerals present in HM concentrates and determining the amounts of each. The method is fairly accurate for the major minerals present, but accuracy decreases for

the minor minerals. Development and refinements of the x-ray microprobe, scanning electron microscope (SEM), associated XRF techniques, and modern computer science have been combined to produce the most accurate and sophisticated means for analyzing HM concentrates. It is now possible to accurately identify each mineral present in a sample, measure each particle's size, chemically analyze it, and then give an accurate percentage for each individual mineral present in the sample, its average chemical composition, and its particle-size distribution.

MINING AND PROCESSING

Zircon is sourced from HM sands mining operations in which the mineralized sand (containing both zircon and titanium minerals) is mined using dredging or dry mining techniques. The choice of method depends primarily on the physical nature of the deposit and the scale of operation. Dredging is the preferred and more economical choice for large-scale operations. Dry mining methods are used for smaller-scale operations in situations where there is inadequate water; where the deposit contains hard, rocky material; or where there is a high clay content.

Such deposits contain from less than 1% HM to more than 10% HM. The remaining material is predominantly clay and silica sand. The proportion of clay, or slimes, in the HM deposits varies considerably. The slimes are first separated from the sand, and the HM are then separated from the silica sand to make an HM concentrate containing in the region of 90% to 95% total HM. These concentration processes employ wet gravity concentration techniques on spiral separators or cone concentrators. The HM concentrate is then transported to the dry separation plant, where the individual minerals are separated from one another by exploiting variations in their magnetic and electrical conductive properties. Further separations are based on either grain size or specific gravity.

The specific processes used for separating zircon from other minerals include the following:

- High-tension electrostatic separation, typically used for separating zircon from rutile
- Magnetic separation techniques, used for separating zircon from mildly magnetic minerals such as leucoxene, monazite, and altered ilmenite
- Gravity separation techniques, using spiral separators, Kelsey jigs, hydrosizers, and air tables to separate zircon from minerals such as kyanite, other aluminosilicate minerals, monazite, and quartz

In many mineral sands deposits, the grains are coated with clays and iron oxides. If these are not removed, they contaminate the final zircon product, contributing to higher iron (as Fe_2O_3) and alumina (Al_2O_3) contents, and also make separating the individual minerals more difficult. The mineral grains may also have organic coatings that can affect the mineral separation and the uses of the zircon product—for instance, in special foundry sand applications. The surfaces of zircon grains are cleaned by mechanical attritioning or by chemical means. Mechanical attritioning processes are often incorporated early in the separation plant flowsheet and are used for cleaning both zircon grains and grains of other minerals. However, with some exceptions, the chemical processes primarily clean the surfaces of the zircon grains to improve zircon product quality.

Specific chemical processes used to remove coatings from the surface of zircon grains are

- The hot acid leach (HAL) process, in which hot zircon is coated with moderately concentrated sulfuric acid and reacted in a kiln, after which the product is attritioned, neutralized, and dried
- The zircon upgrading process (ZUP), which involves heating the zircon to about 400°C , after which it is quenched in dilute sulfuric acid

Both of these processes are effective in lowering the iron content of zircon from more than 0.2% to as low as 0.04% Fe_2O_3 . It is likely that specific grain cleaning processes will become increasingly important as demand for high-quality zircon with low iron content increases and as the availability of naturally clean zircon deposits diminishes.

Iron may also be contained within the zircon grain as inclusions of ilmenite or iron oxides. In such cases, it may be possible to separate grains with high iron content using selective magnetic separation. High-gauss magnetic mineral separation may also be used in certain instances to reduce high levels of U+Th in zircon. This separation, however, usually results in relatively high loss of zircon recovery because of the slight difference in magnetism between the metamict zircons containing high U+Th and the less altered zircon grains.

In some instances, the final zircon product is calcined at approximately 900°C , principally to render the zircon product whiter. Though this does not improve the chemical quality of the material, it can provide a qualitative advantage in marketing the product for certain applications. It may also relieve crystal stresses caused by zircon's natural radioactivity and improve milling characteristics prior to use as an opacifier.

GRADES AND SPECIFICATIONS

Although its theoretical chemical formula is ZrSiO_4 , naturally occurring zircon has the variable formula $(\text{Zr,Hf,U,Th,Y})\text{SiO}_4$. Zircon always contains some Hf, commonly around 2% (as HfO_2), but it can be as high as 4%. Zircon also always contains some U and Th and rare earth elements such as Y. These impurity elements are incorporated into the zircon crystal structure and cannot be removed without destroying the individual zircon grains.

Other impurities found in zircon crystals, such as Al_2O_3 , silica (SiO_2) (other than that included in the crystal structure), and Fe, are usually the result of secondary deposition in cracks and cavities in the zircon grain as a result of precipitation from aqueous solutions. Additional impurities present in commercial zircon products are present as individual grains of other minerals.

Quality specifications for zircon are typically quoted in terms of zirconia content (expressed as $\text{ZrO}_2+\text{HfO}_2$), Fe_2O_3 , Al_2O_3 , TiO_2 ,

and, occasionally, radioactivity (U+Th). SiO_2 content may also be quoted, although it is the free silica content present as quartz that is most important. Physical specifications normally include grain sizing (either as a size distribution or AFS [American Foundrymen's Society] number), bulk density, and residual pH.

Guaranteed levels are normally quoted for the following:

- $\text{ZrO}_2+\text{HfO}_2$: minimum 65.0% to more than 66.0% for ceramic applications
- Fe_2O_3 : maximum levels ranging from as low as 0.04% for premium ceramic-grade quality up to 0.25% for foundry-grade products
- TiO_2 : maximum levels ranging from 0.10% to 0.30%, depending on the grade and application

For certain applications, specific consumers may request other guaranteed levels. For example, maximum Al_2O_3 and phosphate (P_2O_5) levels may have to be guaranteed for certain foundry or zirconia/zirconium applications.

Fe_2O_3 content is often the most common specification in determining the suitability of a zircon product for a particular application. In particular, low Fe_2O_3 content is often requested for ceramic opacifier applications. The commonly accepted maximum level for premium-grade zircon is 0.07% Fe_2O_3 , even though zircon products with higher levels of iron have been used satisfactorily in a number of opacifier applications. Iron content is controlled principally through grain surface cleaning and efficient mineral separation, minimizing contamination by leucoxene and staurolite.

The level of TiO_2 content is principally a function of the extent of contamination by titanium minerals, normally leucoxene or rutile as separate grains. This is controllable by efficient electrostatic separation, but may be affected by the degree of grain surface coatings, which affects electrostatic separation.

High Al_2O_3 content is usually an indication of contamination by aluminosilicate minerals, typically kyanite or sillimanite. These minerals are most effectively separated from zircon using wet or dry gravity separation techniques.

Silica, in the form of free quartz grains, must also be controlled, not only because it acts as a diluent to the ZrO_2 grade but also because it is considered an occupational hazard. Crystalline silica is known to cause lung fibrosis (silicosis) and has also been classified as a carcinogen. Generally, free silica must be reduced to less than 0.1% to comply with local occupational health and safety standards. Free quartz is readily separated from zircon using gravity techniques.

The radioactivity of the zircon is important to zirconium/zirconia producers who must deal with the elevation of radiation in waste streams. The level of U+Th in a zircon product may be influenced by contaminating particles of monazite, which can be removed by magnetic separation and by wet and dry gravity separation processes. However, in most clean zircon products, the U+Th content is a function of the extent to which these elements are present in the zircon crystal structure, and this U+Th cannot be removed by physical processing methods. With some exceptions, chemical processing without disturbing the grain is unlikely to be successful. Therefore, the level of U+Th in the various commercial zircon products is primarily a function of their geological setting.

MARKETS AND USES

Zircon is ultimately used in a wide range of consuming industries (see Figure 1), in varying physical and chemical forms. In its simplest form, zircon is used as a sand, directly from the mineral processing plant at the mine. Refractory products, abrasives, and foundry sands contain zircon in this form.

The majority of zircon is processed further before consumption. It is mechanically ground into either a flour (95% passing 45 μm) or an opacifier (95% passing 5 μm). In this form, zircon is consumed in ceramics, investment castings, television glass, and refractories.

Chemical processing of zircon is less common. Zircon is processed chemically to produce alumina-zirconia-silica (AZS) for use in glass refractories and a range of zirconium chemicals that are used in advanced ceramics, colored ceramic pigments, catalysts, and a wide variety of other minor applications. Zirconium metal is also produced chemically from zircon sand and finds applications in the nuclear industry.

Ceramics

The main use of zircon in the ceramics industry is as an additive to glazes used on ceramic tiles to provide opacity. It can also be added to engobes (an intermediate surface on a ceramic body) or incorporated in the main body of the ceramic body, as with gres porcellanato tiles. The sanitary-ware industry is also a major market for zircon, where it is also added to the high-gloss glaze as an opacifier. Zircon also finds some use in tableware products, but this is a smaller market because transparent glazes are widely used.

Refractories

Zircon is now a specialized refractory material because of its relative cost and availability. It is added to refractory products as zircon sand, zircon-pyrophyllite mixtures, zirconias, or AZS, depending on the industry and application. Zircon-based refractories are used in steel- and glassmaking.

Foundry

Zircon is used as a foundry sand, to form casts in investment casting, on the surfaces of die casts, and in the Cosworth process. In the first three applications, zircon is a relatively minor ingredient, but in the Cosworth casting process, which is used to cast aluminum motor engine heads and blocks, coarse-grained zircon sand is used exclusively. Additionally, some refractory paints, or mold washes, contain 60% to 70% zircon flour.

Glass

Zircon is used in the faceplate panels of color televisions and computer monitors to absorb x-rays generated in cathode ray tubes. Zircon is also used in the glass substrates of liquid crystal displays (LCDs) and plasma display panels (PDPs). These products contain about 1% zirconia but consume only small volumes because the substrates are very thin. Zircon and zirconia are also added to some specialty glasses, such as lead-free crystal glassware, special fiber-glass, and optical fibers.

Other Markets

There are a wide range of small-end-use markets for zircon and its derivatives and hafnium:

- Markets for zirconia—abrasives, electronics, oxygen sensors, gemstones, ceramic pigments, advanced ceramics, catalysts, fuel cells
- Markets for zirconium chemicals— TiO_2 pigment coating, paper coatings, paint driers, antiperspirants, printing inks, and paints
- Markets for zirconium metal—nuclear reactor fuel tubes, chemical industry
- Markets for hafnium metal—component of superalloys used in the aeronautics and space industry, neutron absorber in nuclear reactor control rods

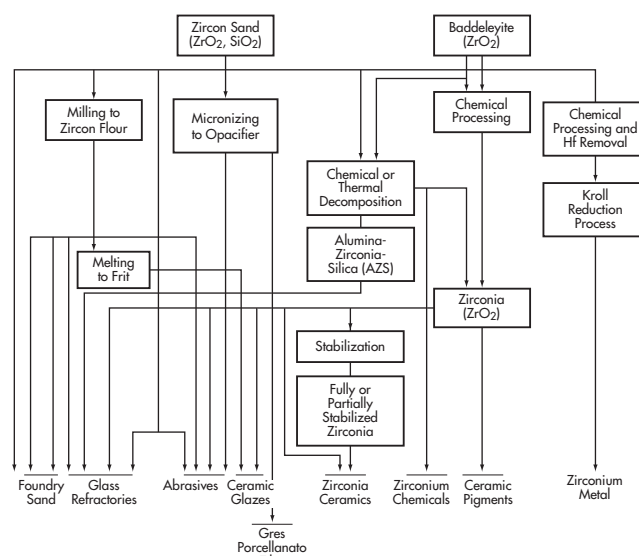

Figure 1. Schematic structure of zircon processing and consuming industries

Figure 2. Zircon consumption by end-use market (2003)

Figure 2 shows the breakdown of principal end uses for zircon in 2003. The ceramics sector is by far the largest consumer of zircon sand, accounting for almost 51% of consumption in 2003. Not only is the ceramics sector the largest end-use market for zircon, it also showed steady growth with a veraging more than 5.0 % per year between 1987 and 2003. It is very clearly the principal driver of zircon demand. A key element in this sector is the role played by the zircon milling groups, principally based in Europe, that dominate the market for zircon. These consumers mill the zircon to flour for use in the manufacture of frits and to very fine opacifier for use in the manufacture of glazes.

The other large-volume markets—namely, the refractory and foundry industries—together account for a further 30% of zircon consumption. Technological advances, however, are reducing the volumes of zircon required and in some cases allowing more cost-effective materials to be used in place of zircon. Although still important markets, there is little expectation of substantial growth in demand in either the foundry or refractory sectors.

More interesting, from a zircon consumption viewpoint, are the smaller markets of zirconia, zirconium chemicals, and TV glass. These higher-value markets for zircon grew at 9% to 13% per year

Figure 3. Zircon consumption by geographical region (1980–2003)

between 1987 and 2003, and demand is now believed to be reaching a plateau; future growth rates are forecast to be substantially lower.

Figure 3 shows the principal geographic markets for zircon from 1980 to 2003. The Asia-Pacific region dominates zircon consumption, accounting for 40.5% of the total in 2003. Within the Asia-Pacific region, China has the highest level of zircon consumption. Europe has always been a large consumer of zircon. In 2003 it was estimated that Europe accounted for more than one third of all zircon consumption, mainly because large European ceramic production centers use zircon in frits and glazes for ceramic products.

Global zircon demand has averaged 2.7% per year compound growth since 1987 and 3.8% per year from 1998 to 2003. During this 6-year period, China showed the strongest growth at 13%, as a result of strong construction activity, housing sector reform that allows private home ownership, and the 2008 Olympics—all of which are combining to boost the demand for ceramic products. The mature North American market declined by an average 4% per year over the same period.

ALTERNATIVE MATERIALS

During periods of zircon shortages, the foundry industry used South African chromite and domestic olivine as zircon substitutes.

Figure 4. Zircon prices 1970–2003, real 2003 US\$

With the exception of a few special applications, the foundries returned to the use of zircon when it became available. Mullite, manufactured by calcining kaolin clay, is also used successfully as a substitute for zircon, both as a foundry sand and mold wash. Japan's steel industry has successfully replaced much of its zircon refractories requirement with high-alumina and magnesium refractory products. Dolomite and spinel refractories can also substitute for zircon in certain high-temperature applications.

Columbium (niobium), stainless steel, and tantalum provide limited substitution in nuclear applications, and titanium and synthetic materials can substitute in some chemical plant uses. Silver-cadmium-indium control rods are used in lieu of hafnium at many nuclear power plants. Zirconium can be used interchangeably with hafnium in certain superalloys; in others, only hafnium produces the desired or required grain boundary refinement.

Unless future zircon supply becomes severely limited, it is unlikely that any substitute with all of its properties will be sought or found.

OUTLOOK

All commercially produced zircon is a co-product of titanium mineral production. However, over the last 40 years, zircon has developed from a low-value by-product of titanium mining to an important co-product that typically accounts for between 15% and 35% of total revenue. Despite its increased value, zircon supply remains dependent on titanium mining. Consequently, the future supply of zircon will depend on the zircon content of the deposits that are developed to meet demand for titanium feedstocks. In recent years, supply has become very short, and this scarcity has prompted companies to promote new projects as "zircon" projects, but the fact remains that the deposits contain more titanium than zircon.

The key to the future level of demand for zircon in consumption is the ceramics industry, which is by far the largest market for zircon and which is forecast to continue at a steady pace.

Future supply may not be sufficient to meet the growing demand for zircon. This could lead to substitution of zircon in certain applications, and pricing pressures will mean that this takes place at the lower-quality end of the market spectrum, particularly in the foundry and refractory industries.

Table 3 clearly shows the imminent problem of insufficient supply, with a shortfall of 100,000 t forecast for 2004, a level likely to continue for some time unless more resources are discovered. This will clearly affect zircon prices, which exhibited a past propensity to spike (as shown in Figure 4), and prices are forecast to increase further in 2005.

The next few years will be another very interesting period in the evolution of zirconium and hafnium markets.

PART THREE

Markets and Uses

Absorbents and Desiccants

Abbas A. Zaman

INTRODUCTION

Absorbents and desiccants are the key materials in many industries dealing with purification, clarification, and separation. Adsorption, which involves the preferential concentration of solutes at an interface, is of great importance in various science and engineering fields. These include waste treatment, pet litter, cosmetics, food products, petroleum, chemical industries, pharmaceuticals, water purification, energy-related industries such as storage of hydrogen for fuel cell technology, separation technologies such as removal of carbon monoxide (CO) from hydrogen, and environmental technologies for meeting higher standards on safety issues and environmental pollutants. In addition, the use of absorbents and desiccants is a convenient method to handle liquid wastes, clean up spills, and eliminate odors.

MATERIALS

A wide range of materials are used as desiccants and absorbents. These can be categorized as industrial minerals and rocks including different kind of clays, and synthetic materials such as zeolites, silica gel, activated carbon, and activated alumina. The world market for activated carbon demand (granules, powder, and felts) is estimated at around \$2.0 billion, growing at an annual rate of 7.5% (Yang 2003). According to Business Communications Company, Inc., and R. Deshpande (2001), the approximate reported figures for annual worldwide sales of some of the adsorbents in 2001 were

Activated alumina	\$91 million
Clays	\$44 million
Granular activated carbon	\$334 million
Silica gel	\$177 million
Zeolites	\$1,100 million

Although minerals and rocks represent only a small portion of the total materials used as absorbents and desiccants, as shown in Figure 1 (Van Kouteren 1994), the most widely used material for this kind of application is activated carbon. Commercial production of activated carbon dates back to the nineteenth century (Yang 2003). During World War I, filters containing carbon black were developed to remove chemicals from air. Activated carbon is widely used in bulk separation of hydrocarbons; purification of gases such as air, nitrogen, hydrocarbons, sulfur dioxide, and halogenated organics; and liquid and water purifications to remove organics, solvents, and inorganics such as arsenic, chromium, and odor species.

*Includes fibers, powders, pulp and paper, and centrifuges

Figure 1. The U.S. fluid conditioning market by type of system

Silica gel and activated alumina are widely used as desiccants because of their large capacity for water adsorption (nearly 40 wt %) and also because they regenerate at low temperatures (150°C) compared with zeolites. The surface of these materials has been modified with different organic ligands for different applications (Vansant, Van Der Voort, and Vrancken 1995).

MINERALOGY

The common mineralogical trait of industrial minerals used as absorbents and desiccants is that these materials all belong to the silicate group. Silicates have an inherent chemical stability and unique molecular structures, which prove to be useful in absorbents. Silica (SiO₂) is the dominant chemical constituent and is present in many different forms. For example, in the clay minerals, it is present in complex tetrahedral and octahedral sheets and/or chains. In diatomite, it occurs in an amorphous form (Van Kouteren 1994).

Diatomite and Perlite

Diatomaceous silica is the preferred name for the primary mineral component that makes up the rock diatomite. Diatomite is a siliceous, sedimentary rock consisting principally of the fossilized skeletal remains of the diatom, a unicellular, microscopic aquatic plant related to algae (Kadey 1983). Fossilized diatom skeletons are made of opaline or hydrated silica (SiO₂•H₂O).

On the other hand, perlite, in its naturally occurring form, is a dense, amorphous, hydrated volcanic glass, generally of rhyolitic

Figure 3. Geometric representation of silica tetrahedron showing (a) a single silica tetrahedron, and (b) the sheet structure of the silica tetrahedra arranged in a hexagonal network

composition (sodium potassium aluminum silicate). Because of its commercial applications, perlite has a dual nomenclature in the industry. It is known by the same name as both the naturally occurring rock and, after processing and thermal expansion, as the lightweight aggregate (Kadey 1983).

Specialty Clays

Compared to other minerals used as absorbents, the clay minerals are much more mineralogically complex. As a general definition, clays are naturally occurring, earthy, fine-grained hydrous silicates (Patterson and Murray 1983). Collectively, they are classified as phyllosilicates, a group of silicate minerals characterized by silica-oxygen tetrahedra linked together in two-dimensional sheets (Thrush 1968).

The phyllosilicate group of clays consists of several minerals, each having different mineralogy, geologic occurrence, technology, and uses. Although the mineralogy is complex, it is easier to think of these minerals as containing crystal structures that can be broken down into two simple building blocks: tetrahedra and octahedra. These building blocks form sheets or layers by joining at the corners (tetrahedra) or at the edges (octahedra) (Moll and Goss 1987), as shown in Figures 2 and 3.

Given these basic building blocks, the variations in how the blocks are arranged yield the various groups of clay minerals. Table 1 lists the major clay mineral groups used as filters and absorbents, along with their commonly used names and mineralogical compositions. The major structural differences between these groups are imbedded in how the building blocks are layered.

Smectite Group

Smectite minerals have a three-layer structure. Two outer layers of silica tetrahedra are attached to a central octahedral layer of hydrous metal oxide (usually aluminum, sodium, magnesium, calcium, or lithium). The layers are combined in a way that the oxygen atoms at

Table 1. Classification of clay minerals including those used as absorbents

Clay Group and Commonly Used Names	Chemical Formula
Kaolinite and Serpentine Group (two-layered structure)	
Kaolinite	$\text{Al}_2(\text{Si}_2\text{O}_5)(\text{OH})_4$
Halloysite	$\text{Al}_2(\text{Si}_2\text{O}_5)(\text{OH})_4 \cdot 4\text{H}_2\text{O}$
Serpentine	$\text{Mg}_3(\text{Si}_2\text{O}_5)(\text{OH})_4$
Micas (three-layered structure. The charge of the three-sheet layer ≤ 2)	
Illite	$\text{K}_2\text{Al}_4[(\text{Si}_6\text{Al}_2)\text{O}_{20}](\text{OH})_4 \cdot n\text{H}_2\text{O}$
Vermiculite Group (three-layered structure with swelling capacity. The charge of the three-sheet layer = 1.2–1.8)	
Trioctahedral vermiculite	$(\text{Mg}, \text{Fe}^{2+}, \text{Fe}^{3+})_6[(\text{Si}, \text{Al})_8\text{O}_{20}](\text{OH})_4 \cdot n\text{H}_2\text{O}$
Smectite Group (three-layered structure, strongly swelling. The charge of the three-sheet layer = 0.5–1.2)	
Montmorillonite	$\text{M}^{+}_{x+y}(\text{Al}, \text{Fe}^{3+})_4\text{Si}_4\text{O}_{20}(\text{OH})_4 \cdot n\text{H}_2\text{O}$
Calcium (nonswelling bentonite)	Same as above with M^{+} being Ca^{2+}
Sodium (swelling bentonite)	Same as above with M^{+} being Na^{+}
Magnesium (saponite)	$\text{M}_x^{+}\text{Mg}_6(\text{Si}_8\text{Al}_x\text{O}_{20})(\text{OH})_4 \cdot n\text{H}_2\text{O}$
Beidellite	$\text{M}_x^{+}\text{Al}_4(\text{Si}_8\text{Al}_x\text{O}_{20})(\text{OH})_4 \cdot n\text{H}_2\text{O}$
Nontronite	$\text{M}_x^{+}\text{Fe}_4^{3+}(\text{Si}_8\text{Al}_x\text{O}_{20})(\text{OH})_4 \cdot n\text{H}_2\text{O}$
M^{+} represents adsorbed alkali cations in the interlayer space.	
Pyrophyllite and Talc Group (three-layered structure, nonswelling. The charge of the three-sheet layer = 0)	
Pyrophyllite	$\text{Al}_2(\text{Si}_4\text{O}_{10})(\text{OH})_2$
Talc	$\text{Mg}_3(\text{Si}_4\text{O}_{10})(\text{OH})_2$
Chlorites Group (four-layered silicate structure, nonswelling. The charge of the four-sheet layer = 1.1–3.3)	
Donbassite	$\text{Al}_2(\text{Si}_8\text{O}_{20})(\text{OH})_4 \cdot \text{Al}_4(\text{OH})_{12}$
Palygorskite and Sepiolite Group (with the layer fibrous structure)	
Palygorskite	$\text{Mg}_5(\text{Si}_8\text{O}_{20})(\text{OH})_2(\text{OH}_2)_4 \cdot 4\text{H}_2\text{O}$
Sepiolite	$\text{Mg}_8(\text{Si}_{12}\text{O}_{30})(\text{OH})_4(\text{OH}_2)_4 \cdot n\text{H}_2\text{O}$

Adapted from Konta 1995.

the tips of the tetrahedra of each silica layer are shared with the octahedral metal oxide/hydroxide layer. A small proportion of the metal cations in the central octahedral layer is replaced by cations of lower valence but similar size. This leads to an electrical charge imbalance that is corrected by the presence of cations held outside and between each of the three-layer units. The electrical charge deficiency of the three-layer units and the presence of the exchangeable cations (commonly sodium or calcium) impart the characteristic expansion properties to the smectite group of clays (Clarke 1985).

Palygorskite and Sepiolite (Hormite) Group

Hormites are markedly different in terms of their structural characteristics in that they form chain-type rather than layered structures. The chain-type yields a fibrous-like structure (Clarke 1985). Unlike the smectite minerals, which have sheets that extend laterally, the sheets in hormite minerals extend only a short distance and then flip up or flip down in a continuous pattern to yield a three-dimensional structure that includes long tubes instead of layers. Because of this structure, hormite minerals do not swell as do smectite minerals. However, crystal lattice substitutions, or exchange capacity, do occur at the broken bonds on the edges of the crystal (Moll and Goss 1987).

Kaolin Group

This group of minerals, consisting principally of kaolinite, forms a two-layer structure. The two layers are composed of tetrahedra and octahedra sheets. The tetrahedra contain silicon and oxygen and the octahedra contain aluminum, oxygen, and hydroxyl, arranged in sheets. The apexes of the tetrahedra join with the octahedra to form the two-layer structure with water molecules between the two layers. These sheets are generally neutral, but on the edges, where broken bonds exist, unbalanced charges are also found. These sites are areas where cation exchange can occur (Moll and Goss 1987).

Sand and Gravel

In the strictest sense, these two materials are defined by size rather than by composition or mineralogical makeup. Sand and gravel consist of separate grains or particles of detrital rock with a particular size range of $1/16$ to 2 mm in diameter. For filter and absorbent applications, however, sand consists mainly of pure, rounded quartz (SiO_2) grains (Davis and Tepordei 1985), and gravel typically consists of rock fragments.

Minor Minerals

Other minerals used as filters or absorbents include vermiculite, talc, ball clay, crushed limestone, gypsum, ilmenite, and garnet. Vermiculite, talc, and ball clay are also in the phyllosilicate group. As a consequence, these minerals, especially vermiculite, are commonly used in certain absorbent applications. Such heavy minerals as garnet and ilmenite (and sometimes anthracite coal) are often used as filter media in wastewater treatment plants. Calcium carbonate (especially as lime) and gypsum are two nonsilicate minerals that find limited applications as absorbents.

DOMESTIC PRODUCTION AND USE OF CLAYS

According to the U.S. Geological Survey (2004), clay and shale production was reported in 2003 in all states except Alaska, Delaware, Hawaii, Idaho, New Hampshire, New Jersey, Rhode Island, Vermont, and Wisconsin. Approximately 760 clay pits or quarries were operated by about 240 companies, and the leading 20 firms supplied about 50% of the tonnage and 79% of the value for all types of clay sold or used in the United States. Remaining essentially unchanged from 2002, U.S. production was about 39.3 Mt and was valued at \$1.6 billion. Major domestic uses for specific clays were estimated as

- Ball clay—41% floor and wall tile, 25% sanitary ware, and 34% other uses
- Bentonite—25% pet waste absorbent, 21% drilling mud, 21% foundry sand bond, 15% iron ore pelletizing, and 18% other uses
- Common clay—56% brick, 17% cement, 17% lightweight aggregate, and 10% other uses
- Fire clay—75% refractories and 25% other uses
- Fuller's earth—74% absorbent uses and 26% other uses
- Kaolin—54% paper, 17% refractories, and 29% other uses

Table 2 presents data for the production, imports, and exports of different clays in the United States.

Overall production of clays in the United States, including ball clay, bentonite, common clay and shale, fire clay, fuller's earth and kaolin, decreased by 3% in 2000 to 40.8 Mt. Exports increased about 9% to 5.3 Mt, and imports increased about 6% to 96,000 t (Grahl 2002). Bentonite and fuller's earth are the clays most commonly used as absorbents. The other clay statistics are included in the table to show the overall market.

Figure 4. U.S. consumption of ball clay, 1999–2000

Between 1996 and 1999, the ball clay industry sustained an exceptional growth rate of 7.6% per year. The robust economy and associated booming construction industry prior to the latter half of 2000 resulted in healthy sales of sanitary ware and other ceramic products that use ball clay. In 2000, domestic consumption increased compared to 1999 for floor and wall tile, 12%; refractories (including firebrick, blocks, shapes, high-alumina brick and specialties, and kiln furniture), 38%; and miscellaneous ceramics (including catalysts, electrical porcelain, fiberglass, fine china/dinnerware, glazes, and mineral wool), 52%. Declines in consumption were recorded, however, for pottery (81%) and sanitary ware (12%; see Figure 4.)

The recession that began in March 2001 resulted in declining consumption of industrial products in many sectors. Construction was one of the last business segments to be affected. Major business consolidations have occurred over the past several years, resulting in five major competitors—Imerys (based in France with locations worldwide), Unimin (based in Belgium with locations worldwide), WBB Minerals Ltd. (based in the United Kingdom), H.C. Spinks (based in the United States), and Old Hickory Clay (based in the United States)—dominating the U.S. ball clay market. Competition, coupled with the slowing economy, appears sufficient to minimize any significant price increases over the next several years.

The production of common clay and shale declined slightly (4%) to 23,700 t in 2000. Of this amount, the majority was supplied from North Carolina (10%), Texas (9%), Alabama (9%), Georgia (6%), and Ohio (6%). Use of common clay and shale increased 23% in ceramic floor and wall tile, but declined nearly 40% in refractory applications. Demand for common clay and shale in heavy clay products (including extruded brick, drain tile and sewer pipe, flue linings, and miscellaneous clay products) declined about 2% compared to 1999 levels.

Production of fire clay increased about 16% in 2000 to 476,000 t, with the largest increase (53%) in heavy clay products.

Figure 5. U.S. kaolin consumption by end use (ceramics), 2000

Production of fuller's earth also increased by about 12% to 2.9 Mt, but it was uncertain how much of that amount was used in ceramic applications. Data were unavailable for the use of bentonite in ceramics in 2000.

The kaolin industry has been mostly stagnant over the last several years. Production in 2000 slipped 4% to 8.8 Mt. Of this amount, 18% (1.5 Mt) was used in ceramic applications (see Figure 5). This was 3% lower than the share held by ceramics in 1999 (1.9 Mt), and the overall quantity of kaolin used in ceramics also decreased by about 18%. Segments posting the biggest declines were electrical porcelain (down 38% compared to 1999) and miscellaneous refractories (down 56%). Other applications for kaolin included fillers, extenders, and binders (primarily for paper and paper coatings), 53%; chemical manufacture, 0.4%; portland cement, 1%; and miscellaneous, 6%. Exports comprised 31% of overall production at 2.7 Mt, an 11% increase over 1999 levels. Import information was unavailable.

As with ball clay, kaolin consumption in sanitary ware and other ceramic products used in construction is expected to decline as the construction industry slows. Kaolin consumption in fine china and dinnerware is expected to remain relatively steady.

Despite several significant business consolidations over the last several years, approximately 25 companies in nine states mine kaolin. Ongoing competitive forces coupled with a soft economy will probably temper any desire by producers to increase kaolin prices in the near future.

DISTRIBUTION OF MAJOR DEPOSITS

United States

The United States is home to major deposits of all the industrial minerals and rocks used as absorbents. In fact, the diatomite, kaolin, attapulgite, and sand deposits are world class in terms of size and purity. These deposits, however, occur in select areas of the country. Diatomite and perlite deposits are in the West, the specialty clay deposits are in the South, and sand and gravel deposits occur in all regions, as shown in Figure 6. The biggest disadvantage in terms of deposit location and market demand is that diatomite and perlite are mined in the West and the demand is concentrated in the Midwest and the East. Table 3 is a comparison between the mine production in the United States and different countries around the world.

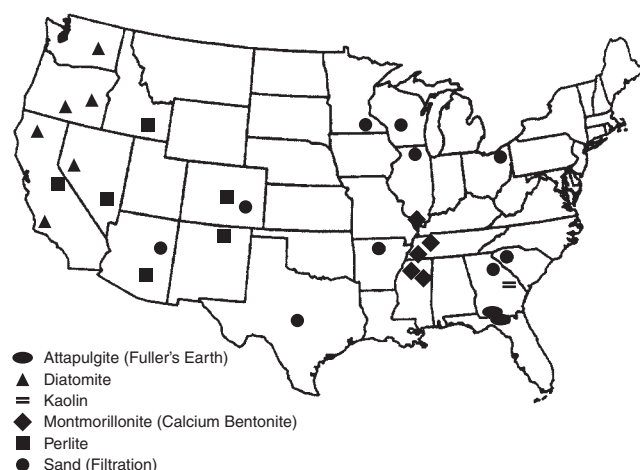

Figure 6. Major producing locations of industrial minerals and rocks used as filters and absorbents

Diatomite and Perlite

All of the commercial deposits of diatomite and perlite occur in the western United States. Diatomite is currently mined in the states of Arizona, California, Nevada, Oregon, and Washington. Greater than 50% of U.S. production is mined from the world-class deposits at Lompoc, California (Miles 1990).

New Mexico accounts for about 85% of the perlite mined in the United States, with the remaining 15% mined in Arizona, California, Colorado, Idaho, and Nevada. Because expanded perlite has a very low bulk density and the majority of perlite is consumed in the East, crushed perlite ore is typically transported to expander plants, which are located close to major end-use markets (Meisinger 1988).

Specialty Clays

Commercial deposits of specialty clays used as filters and absorbents are, for the most part, located in the Southeast. Mississippi,

Missouri, and Tennessee account for the majority of calcium montmorillonite. Florida and Georgia account for all of the attapulgite production.

Sand and Gravel

The occurrence of sand and gravel deposits are pervasive throughout the United States. From a strictly geologic view, the quantity of sand and gravel is essentially inexhaustible (Dunn 1983). Although this is true for gravel used in filtration, it is not true for sand. The sand that is used in filtration applications has rigid specifications as to the purity, size, and shape of the individual grains. As a consequence, the major deposits that naturally yield such material are limited to locations in northern Illinois and central Texas (Van Kouteren 1994).

The Rest of the World

A review of the USGS mineral production statistics indicates that no one country dominates in producing materials used as filters and absorbents. There are, however, a number of countries that are major producers of these raw materials.

PHYSICAL AND CHEMICAL PROPERTIES

Clay minerals used as absorbents and desiccants have a number of similar chemical and physical properties. They must be chemically stable with a physical structure that allows the storage and flow of liquids in the structure. Chemical analysis of the major materials used as adsorbents and desiccants is shown in Table 4 (Van Kouteren 1994). Silica, the main constituent, is responsible for chemical stability. The relatively open or porous structure of these materials results in low bulk densities.

The properties and technical application of clay minerals mainly depend on the mineral composition, size distribution, degree of consolidation, and processing conditions (Konta 1995). Properties of clay minerals depend mainly on the structure and chemistry of the crystal and also on the state and distribution of the electrostatic charge of the structural layers. The ionic substitution in the octahedral and tetrahedral sheets will result in a negative charge, which is naturally compensated by cations such as K^+ , Na^+ , Ca^{2+} , Mg^{2+} , and H^+ adsorbed in the interlayer space. larger pore volume with a new microstructure can be prepared by exchanging any of these cations with a desirable cation and also by removing ions from the octahedral or tetrahedral sheets (Konta 1995).

Kaolinite and Serpentine Group

The most common mineral in this group is kaolinite. Its crystal has the unit cell chemical composition of $\text{Si}_2\text{Al}_2\text{O}_5(\text{OH})_4$ and consists of alternating layers of silica tetrahedra and alumina octahedra. Each kaolinite particle consists of several sheets of twin layers held together with hydrogen bonds. The aspect ratio of kaolin particles, which are plate-like in shape, may vary from 5 to 15, depending on the mechanical treatment of the particles (Konta 1995; Weaver and Pollard 1973; Sjöberg et al. 1999). Physical and chemical properties of kaolin, which depend on several factors such as geological conditions and mineralogical composition, determine the use of kaolin in different applications. The best commercially usable kaolin deposits are located in Georgia and South Carolina in the United States, the Amazon region of Brazil, and the Cornwall Area of southwestern England (Pickering and Murray 1994).

Kaolin is a white powder and its pure crystal, called kaolinite, is hexagonal in shape (see Figure 7). There is a significant charge difference between the basal plane and the edge of the particles resulting from the differences in chemical composition. Kaolin edges contain both silica and alumina-like charge sites, and the faces contain only silica-like charge sites, which are expected to remain negatively charged above pH 3.0. The edges are positively charged at low pH, but progress through an isoelectric point to possess a negative charge at high pH (Johnson, Russell, and Scales 1998; Johnson et al. 2000). As a result of this difference, in the absence of dispersing agents, electrostatic edge-to-face attraction causes agglomeration of the particles in the form of a cardhouse-type structure (even at very low volume fractions) depending on the pH of the dispersion (Herrington, Clarke, and Watts 1992). Results of earlier work (Zaman, Tsuchiya, and Moudgil 2002) indicate that negatively charged agents such as polyacrylic acid (PAA) adsorb on positive sites present on the edge of kaolin particles.

The main applications of kaolin is in the paper industry where it is used to improve brightness, opacity, and printability of paper; as functional fillers and extenders in different products such as plastics, rubber, paint, and ink; in ceramics in the tile, white ware, sanitary ware, insulators, and pottery markets; and as a raw material in the production of fiberglass. A relatively small amount of kaolin is used as a dust-dispersal adsorbent for pesticides (Khandal et al. 1992) and as a mildly acting sorbent in the manufacture of linoleum and other floor-cloth cement (Konta 1995).

Kaolinite is a hydrophilic material and can be dispersed in water using anionic inorganics, polyelectrolytes, and surfactants. Adsorption of polymers and surfactants as a function of pH, ionic strength, and polymer charge on the surface of kaolin has been studied (Sastry, Sequaris, and Schwuger 1995; Lee, Condrate, and Reed 1996). Understanding the interaction mechanism of the charged species with the active sites on the surface of the particles is important in terms of the application of kaolin in different processes. The surface of kaolin can be modified to make it hydrophobic or organophilic for different applications such as functional fillers in plastics and rubber.

Smectite Group

The smectite group of clay minerals has a three-layer structure formed through the decomposition of volcanic glass. In these minerals, a central octahedral layer of hydrous metal oxide (usually

aluminum, sodium, magnesium, calcium, or lithium) is sandwiched between two other layers of silica tetrahedra. Often, alumina substitution for silica in the tetrahedral sheet and iron and magnesium substitution for aluminum in the octahedral sheet creates a net positive charge imbalance in the 2:1 layer (Murray 2000). This charge deficiency is balanced by exchangeable cations such as sodium, calcium, lithium, and magnesium adsorbed between the unit layers and on the edges. The mineral in the smectite group is sodium montmorillonite (see Figure 8) if the dominant exchangeable cation is sodium, and it is calcium montmorillonite if the exchangeable cation is calcium. The smectite group can be classified as montmorillonite, beidellite, nontronite, and saponite.

Calcium montmorillonite has very strong adsorptive properties and is widely used in various processes for removing impurities and as an additive sorbent in different products (Konta 1995). Both sodium and calcium montmorillonites are used in binding animal feed into pellets and both act as absorbents for bacteria and certain enzymes. Montmorillonite is also used as a pet waste absorbent, which may be treated with deodorants and bactericides. A variety called "clumping litter" uses a mixture of calcium-bentonite granules and sodium bentonite. The sodium bentonite swells and clumps when the waste moisture contacts the litter, which makes for selective and easy waste removal from the litter box (Murray 2000).

Calcium montmorillonite is largely used to decolorize, deodorize, and remove impurities from vegetable, animal, and mineral oils, and fats and waxes. Acid-activated calcium montmorillonite is used for filtering and decolorizing oils (Murray 2000; Odom 1984). Calcium ions from the surfaces and edges of the layers will be removed when calcium montmorillonite is treated with sulfuric or hydrochloric acid, which increases the overall negative charge. Acid-activated clay is more effective in removing anionic color species from the oil.

A moderately large amount of natural smectite clay is used to remove colloidal impurities from wine. These impurities are positively charged and adsorb on negatively charged smectite clays. In the clarification of wine, beer, vinegar, and fruit juices, sodium montmorillonites having a light or white color with high dispersibility are preferred. A relatively new market for acid-activated clay is in animal feed, where it absorbs mycotoxins (Murray 2000).

Other adsorbent and desiccant applications of the smectite group, including calcium bentonite, sodium bentonite, acid-activated bentonite, and organophilic bentonite (Murray 2000; Konta 1995), follow. Members of the smectite group are used

- As pillared clays for specific catalyst and absorbent uses
- As a dry detergent for the sorption of impurities
- For the removal of alkaloids and insecticides from vegetable extracts
- As an anti-irritant, and in industrial creams and organic medications in pharmacy
- As a sorbent in soaps, polymers, and construction materials
- For removal of metallic and other ions from water
- For the sorption of sulfur, nicotine, and other impurities from the atmosphere
- As a carrier of substances such as codeine phosphate in pharmacy
- For the removal of oxidation products from lubricating oils
- For water purification
- In different food industries such as in sugar and wine production
- For removal of pigments from fats

Figure 9. SEM image of palygorskite showing elongated particle shape

Palygorskite and Sepiolite

Palygorskite (see Figure 9) and some other clays are termed as fuller's earth because of their sorptive and bleaching properties. Attapulgite, which is a hydrated magnesium silicate mineral with a slight substitution of magnesium by aluminum, is the trade name for palygorskite. Its crystal structure is layer fibrous. The chemical structure of sepiolite is almost the same as palygorskite except it has a slightly larger unit cell (Murray 2000).

Palygorskite and sepiolite are excellent absorbents and are used in many applications that utilize this property (Murray 2000; Konta 1995). The major applications are in the manufacture of pesticides; as floor absorbents; in agricultural carriers; in bedding for small animals; as anticaking agents; for removal of oil and grease; for purification of sugar; for decolorization and purification of petroleum derivatives; in wax and paraffin; in lubricating oils; for purification of oils and animal fats; as environmental absorbents; and as a natural decolorizing agent, particularly for mineral oils (Galan 1996). Another use of these materials is for environmental applications as barrier clays. A mixture of palygorskite and sodium montmorillonite works well to prevent movements of liquids through the barrier and to absorb heavy metals and toxic pollutants from landfills and industrial wastes (Murray 2000).

Attapulgite is another clay mineral that belongs to the palygorskite group and is widely used as an absorbent. Approximately

939,500 t of attapulgite were produced around the world in 1999, with the United States accounting for 75% (725,000 t), valued at \$80 million. The estimated overall global production of fuller's earth, including attapulgite, montmorillonite, and sepiolite, is just over 3.3 Mt. In the United States, attapulgite has an average value of \$110 per t. Global demand for the material is sensitive to oil drilling activity. U.S. producers saw a decline in the sale of attapulgite from 793,000 t in 1998 to 725,000 t in 1999. Major markets for attapulgite are pet waste absorbents, oil and gas absorbents, pesticide carriers, cement fertilizer carriers, drilling mud, gypsum products, animal feeds, and adhesive applications.

An overview of the market for sepiolite shows that Spain was the largest producer with an estimated production of 750,000 tpy in 1998. Other producers are Turkey at a rate of about 15,000 tpy, the United States at a rate of about 40,000 tpy, and China at a capacity of about 15,000 tpy. Sepiolite is mainly used in cat litter, industrial absorbents, animal feed additives, and carriers for insecticides and herbicides. The expected percentage increases for the consumption of sepiolite over 5 years are in technical applications, +17%; in industrial applications, +20%; in cat litter production, +11%; and in animal feed manufacture, +28%. More than 70% of sepiolite output is used to produce pet litter, mainly cat litter. European demand for sepiolite in animal feed applications is expected to grow by more than 15%. Cat litter usage is likely to have lower growth.

OTHER MATERIALS

Other materials used as adsorbents include diatomite, perlite, sand, and gravel. Diatomite and perlite have cell structures that form microscopic voids. As explained previously, diatomite is a siliceous, sedimentary rock consisting of the fossilized skeletal remains of the diatom plant related to algae (Kadey 1983). Perlite is a dense, amorphous, hydrated volcanic glass, generally of rhyolitic composition. In industry, it is processed and thermally expanded as the lightweight aggregate (Kadey 1983). In 1997, the total market for perlite was 1.66 Mt; United States, 773,000 t; China, 250,000 t; former U.S.S.R., 90,000 t; Denmark, 95,000 t; France, 80,000 t; and South Korea, 53,500 t. The mineral is used mainly for filtration and as an absorbent. It is used in the manufacture of beer and wine. Demand in developed countries is relatively flat but is expanding in developing countries. Diatomite is losing market share for brewing applications to ceramic polymerics and carbon membranes, and it is under pressure from bentonite for absorbent applications. Mallina Holdings has opened a new diatomite plant in western Australia. This has a capacity of about 20,000 tpy. A 10-Mt diatomite deposit at Akhaltsikhe, Republic of Georgia, is to be developed by a joint venture between a U.K. company and a local business. Breakdown of diatomite usage in the United States is beer, 7%; wine, 2%; fruit juice, 3%; sugar, 4%; pharmaceuticals, 2%; exports, 36%; and other, 46%.

Sand and gravel consist of separate grains or particles in the size range of $1/16$ to 2 mm in diameter. For absorbent applications, sand consists mainly of pure, rounded quartz, and gravel consists of rock fragments (Davis and Tepordei 1985; Van Kouteren 1994).

PROCESSING AND SPECIFICATIONS

The processing of clays for use in absorbent applications is fairly similar for attapulgite, montmorillonite, specialty clays, and kaolin. Because clay ore contains up to 60% water, the main objective for processing is to remove water and to reduce the material to the appropriate size. Before the crude clay is dried, it must first be passed through shredders to reduce it to fist-sized pieces for feed to a dryer (Moll 1986).

Proper drying techniques are essential for developing and maintaining the open structure in montmorillonite and attapulgite. At temperatures between 100°C and 200°C, water in the interlayer region of montmorillonite or in the tubes of attapulgite begins to evaporate. At higher temperatures, certain tightly bound water molecules in attapulgite begin to evaporate. Between 500°C and 800°C, the hydroxyl ions begin to combine to form water, which leaves the structure (Moll and Goss 1987).

Once the clay is dried, the material is typically crushed in a corrugated roller or hammer mills and passed over large shaking screens. Oversize material goes back to the crushers, and undersized material goes to the next set of smaller sized screens to produce increasingly smaller granule sizes. These smaller products are typically destined for the pet litter and floor absorbents markets (Moll 1986).

The key properties for clays used as floor absorbents are proper granule size, low bulk density, the ability of the product to absorb liquids readily and rapidly, and durability (so that the granules do not break down in normal shipment and use). Floor absorbents, mainly used for oil and grease, are sold in sizes ranging from 4.00 to 0.43 mm. The other key properties typically are a bulk density of about 625 kg/m³ and the ability to absorb about 65% to 100% of their weight in water or oil (Moll 1986).

In cat litter, the pH and size are the important factors that affect the clay's performance. Low pH products are more effective in controlling the fermentation of urea in cat urine. The size of clay granules is important for avoiding dustiness in use and tracking by the cat. A common size range for cat litter products is often 4.75 to 0.60 mm.

Another key property is surface acidity, also known as Lewis acidity. The surface acidity of the clay granules can cause degradation of some chemicals absorbed into the granule. To prevent the degradation, formulators must measure the strength of the Lewis acid sites to determine how much deactivation is required. High surface-acidity clays, measured by the Hammett acidity function unit (pKa), are deactivated with alcohols or glycols to neutralize the acid sites (Moll and Goss 1987). Table 5 presents examples of the important specifications for carrier materials.

TESTING

As is common with most industrial minerals, the testing procedures by which processed minerals and aggregates are evaluated and standardized are designed to quantify an attribute required in the performance of a product (Kadey 1983).

The important characteristics to measure include a clay's ability to absorb liquids easily and quickly, to have a high liquid-holding capacity, to have granules that do not break down during shipment, and to have relatively low bulk densities. Standard tests and techniques to measure a granule's maximum absorption and resistance to attrition are outlined by federal specifications P-A 1050A and P-A 1056A, respectively. In addition, agricultural carriers undergo a liquid-holding capacity test. The Rhone-Poulenc method MP-12 is a test that measures the amount of liquid the granules can absorb without sticking together (Moll 1986).

In filtering and clarifying applications, the final color of the bleached oil is the critical property. Test methods for evaluating montmorillonite and other types of fuller's earth for bleaching edible oils are outlined in the American Oil Chemists' Society (AOCS) official methods Cc 8a-52 and Cc 8b-52. These specifications contain instructions on bench-type tests, including stirring time, heating rates and temperatures, approved equipment, quantities of clay and raw oil required, and other items (Patterson and Murray 1983).

USE OF ABSORBENTS AND DESICCANTS

Industrial minerals and rocks are used in many absorbent and desiccant applications. On a tonnage basis, the majority of the minerals, including sand, diatomite, perlite, attapulgite, and montmorillonite, find such end uses as municipal waters, food products, chemicals, pet litter, oil and grease, and carriers.

The use of specialty clays in the pet litter market has proven very effective in absorbing liquid pet waste and related odors. Specialty clays used for pet litter have the ability to absorb large quantities of liquid cat waste and retard the formation of ammonia, which is created when urea from cat urine ferments (Harris et al. 1989).

Any user of oil and grease or machinery requiring oil and grease may ultimately require specialty clays to absorb and control spills. Slippery films of oil and grease as well as puddles of water and other chemicals often create dangerous conditions on the floors of machinery repair shops, factories, service stations, and numerous large and small industrial facilities (Harris et al. 1989). Specialty clays can absorb up to their own weight in oil, grease, water, and a variety of other chemicals. The clays also are safe, absorb rapidly, and can be cleaned up using a broom or shovel (Moll 1986).

Specialty clays used as mineral carriers have a wide variety of applications in the field of agricultural chemicals. Most pesticides, including herbicides, fungicides, and insecticides, are highly toxic and typically require only a kilogram per hectare (Moll 1986). The primary function of these carriers is therefore to dilute high-potency chemicals to a spreadable field concentration and to apply them to a location where pests can be destroyed while damage to desirable plants, wildlife, and the environment is minimized (Swayer 1983).

The two main types of mineral carriers are absorbent and non-absorbent. The absorbent carriers, which account for the majority of demand, have a highly porous structure that accounts for their high absorptivity and low density. The nonabsorbent types provide only enough surface area to carry the chemicals and typically have high bulk densities, which limits the amount of chemicals they can carry. Montmorillonite, attapulgite, and diatomite comprise the absorbent carriers, and such minerals as ball clay, calcium carbonate, quartz sand, and talc are considered nonabsorbent (Moll and Goss 1987).

In fertilizers, clays are also used as anticaking additives in dry fertilizer mixes. The anticaking function of the clay works by coating fertilizer particles and absorbing solvents or water that may be present. This reduces the formation of crystals that often bind particles and cause caking problems (Harris et al. 1989).

The most significant other absorbent market for specialty clays is desiccants. Clay desiccants are used to adsorb moisture

from the air enclosed in such packaged products as military equipment and electronic components. This helps prevent corrosion of the product and retards the formation of mildew. The desiccants are made up entirely of calcium montmorillonite clays that are oven-dried, crushed, and packaged in bags or canisters. These products are most effective in conditions of moderate relative humidity (15% to 40%) and are generally preferred because of their ability to adsorb more than 20% of their equivalent weight in water without any apparent change in size, shape, or texture. Furthermore, they are also available at a relatively low cost (Harris et al. 1989).

NEW APPLICATIONS, MARKETS, AND FUTURE TRENDS

The microporous adsorbents industry is a mature industry with a wide variety of products satisfying the requirements of well-established applications. The expanded scope and applicability of environmental regulations, however, along with improving living standards around the world, are stimulating significant increases in demand for these products. In addition to environmental forcers, newly invented, specialized, microporous adsorbent products are creating novel market opportunities in the electronics manufacturing and biomedical industry sectors.

According to a study released in 2001 by Business Communications Company (BCC) Inc., the market value for inorganic microporous adsorbents was estimated at nearly \$1.78 billion in 2001. This total, which comprises the top five and other types of inorganic microporous adsorbents, is forecast to increase at an average annual growth rate (AAGR) of 3.1% to reach \$2.08 billion by 2006.

Water and air purification applications in the environmental pollution control industry consume the majority of GAC (granular activated carbon) production. GAC constitutes nearly one fifth of the total market size and is projected to grow at an AAGR of 3.8%. Its projected growth rate will be negatively affected by relaxed environmental legislation as well as dumping activity from foreign nations.

As shown in Figure 10 and Table 6, zeolites account for the largest market, with nearly 62% of the total market, and thus heavily influence overall growth rates. Their applications range from detergent builders to high-end catalyst supports in the chemical and petroleum industry. Overcapacity in low-end zeolites and reduced obsolescence of improved high-end products will limit the zeolite market's average yearly growth rate to 2.5% in the next 5 years.

Silica gel adsorbents and activated alumina are expected to have the highest AAGR of 4.8% each, with a projected increase from \$177 million and \$91 million in 2001 to a 2006 value of \$224 and \$115 million, respectively. Silica gels are the most common

desiccants and drying agents, and their growth rate will be fueled by applications in health care, building materials, and the high-end paper manufacturing industry. Activated alumina adsorbents are used as common catalyst support in the chemical processing industry. Their application in chromatographic separation columns is expected to accelerate in the biochemical sector.

Usage of clays as adsorbents is projected to grow at a rate of 3.4% to a market size of \$52 million in 2006. Clays are often used as adsorbents where purity is not a primary concern. Development of pillared intercalated layered clay may offer a niche commercial opportunity. The adsorbent materials discussed have attained best available technology (BAT) status in many of their prominent applications. Although they have achieved significant penetration in those application segments, innovation activity remains brisk.

SUBSTITUTE MATERIALS

Substitute materials for adsorbent minerals consist of such organic materials as sawdust and ground alfalfa, corncobs, and citrus fruit rinds (Van Kouteren 1994). Although these materials are typically less expensive, they are not as effective as specialty clays. On the other hand, such synthetic materials as molecular sieves, silica gel, precipitated silica, and nonwoven polyethylene fabrics are very effective but are expensive. In more limited cases, other mineral products such as vermiculite, gypsum, lime, sand, and zeolites are used in specific applications where low cost and/or high performance is desired. Other substitutes include diatomite and perlite, especially in the western United States because of the transportation cost advantage that they have over clays (Harris et al. 1989).

Polyethylene fabric has had the largest impact on the demand for mineral absorbents. These nonwoven fabrics have a natural affinity for petroleum-based products and as a result they can absorb up to 20 times their weight of oil and grease. The use of these materials has grown as a result of the classification of spent clay as a hazardous material and the subsequent disposal costs associated with these clays. The big advantage of these nonwoven fabrics is that they can be incinerated with less than 1% ash remaining (Harris et al. 1989).

ENVIRONMENTAL AND HEALTH REGULATIONS

Governmental regulations concerning crystalline silica have had an adverse effect on the demand for diatomite. This trend began in 1988 when the International Agency for Research on Cancer (IARC) classified crystalline silica as a probable carcinogen. The classification triggered regulation of crystalline silica at a threshold concentration of 0.1% in materials under the IARC's Hazard Communication Standard (Miles 1990).

The diatomite and other minerals suppliers responded to this in a number of different ways, including worker and user training programs, product labeling, and dust reduction programs. The diatomite industry also created the International Diatomite Producers Association (IDPA) to study and issue reports on health, safety, and environmental issues related to the use of diatomite. Other mineral and chemical producers formed a Chemstar Crystalline Silica Panel. The panel, formed in 1989 and sponsored by the American Chemistry Council (ACC), works with government agencies to avoid random banning of minerals suspected of being hazardous.

Another governmental regulation that has adversely affected the demand for minerals and rocks used as filters and absorbents was the 1991 Environmental Protection Agency ban on disposing oil-containing wastes in landfills. This ruling caused some consumers of clays for oil and grease absorbents to switch to other products, mainly because organic products could be incinerated instead of placed in landfills. Clay suppliers are currently fighting to have new tests approved for measuring the leaching or leaking of absorbed oil from clay products. Under the current regulations, a toxicity test renders the clays hazardous, but if proposed liquid release tests are accepted, the absorbent minerals may prove to be less of a hazard (Van Kouteren 1994).

SELECTION OF ADSORBENTS AND DESICCANTS

This section briefly reviews the criteria for the selection and design of adsorbents. More detailed information can be found in a recent book on adsorbents by Yang (2003).

The selection of a proper adsorbent for a given application is a complex problem. Adsorbents are designed based on the adsorption isotherms, which are calculated based on interaction potentials and adsorbent structures. There are three basic types of contributions to the adsorbate–adsorbent interactions: dispersions, electrostatics, and chemical bonds. Weak chemical bonds involving π electrons have recently been explored for the design of new and highly selective sorbents. Adsorption occurs when the interaction potential energy is equal to the work done to bring a gas molecule to the adsorbed state. Many researchers have discussed the individual contributions to the total potential energy in detail by (e.g., Barrer 1978; Israelachvili 1992; Masel 1996). Five different types of interactions contribute to the potential: (1) dispersion energy; (2) close-range repulsion energy; (3) induction energy (interaction between electric field and an induced dipole); (4) interaction between electric field and a permanent dipole; and (5) interaction between field gradient and a quadrupole. The first two are nonspecific interactions and nonelectrostatic in nature, and the last three arise from the

charges on the solid state. The most important property that determines nonspecific interactions is the polarizability of the surface and magnetic susceptibility. The van der Waals radii of the interacting pairs is defined as an equilibrium distance at which the sum of nonspecific interactions is equal to zero. Polarizability, electronic charge, and van der Waals radius are the most important parameters that must be considered in designing adsorbents. Alkali and alkaline earth metal atoms have very high polarizabilities and, when present on the surface, can cause high potentials. When these elements are present as cations, the polarizability is significantly reduced (Yang 2003).

The van der Waals radii of the surface atoms and electronic charges determine electrostatic interactions and are crucially important factors when considering ion-exchanged zeolites and molecular sieves as sorbents (Yang 2003).

Other criteria for selection of adsorbents are the pore size and geometry. The interaction potential between a molecule and a flat surface is greater than that between two molecules or atoms because molecules interact with all adjacent atoms on the surface. When a molecule is placed in a pore of a given shape (i.e., cylindrical surface), it interacts with different sides and the potentials are greater because more surface atoms interact with the adsorbate molecules. Rege and Yang (2000) have calculated the threshold pressure for adsorption in different pore sizes and geometries for nitrogen on carbon using the model that was developed by Horvath and Kawazoe (1983). These results (Yang 2003) indicate that attractive forces acting on the adsorbate molecules are strongly affected by the size and shape of the pores.

Minerals Used in Formulating and Manufacturing Catalysts

Geoffrey E. Dolbear, John S. Magee, and Thomas Shaniuk

INTRODUCTION

Catalysts are designed or preengineered materials that, by their presence, change the nature of chemical reactions. They speed up or drive a reaction toward a desired product while typically not being consumed in the process. Catalysts are either homogeneous or heterogeneous. The former consists of one uniform, harmonized material whereas the latter is made up of two inseparable components: a *support* that can be inert or active, and an *active agent*, usually a precious or base metal. Some catalysts may contain several components, each designed for a different function.

The field of catalysts and catalysis is often broken into two broad areas: refining and industrial. Refining, of course, refers to catalysts used specifically in converting crude oil and its fractions into transportation fuels and various coproducts such as lubricating oils. This is a large area but relatively easy to define. In contrast, the industrial catalyst sector is a very broad one, encompassing all catalysts used in making chemical products ranging from polymer intermediates to pharmaceuticals.

The concept of catalysis as a method of controlling the rate and direction of a chemical reaction has captured the imagination of scientists and technologists since 1835 when Jöns Jakob Berzelius coordinated a number of disparate observations on chemical transformations by attributing them to a “catalytic force” and coined the term *catalysis* to refer to the “decomposition of bodies” by this force (Stell 2003). The first heterogeneous catalytic process of industrial significance, introduced about 1875, used platinum to oxidize SO_2 to SO_3 , which was then converted to sulfuric acid by absorption in an aqueous solution of the acid (Magee and Dolbear 1998).

Today, catalytic processes, and the chemicals derived from these processes, touch every part of daily life. Many chemicals are produced through industrial-scale application of catalysis. Automobiles run on gasoline fuels produced by fluid catalytic cracking (FCC) catalysts made from processed kaolin clay. Emissions from internal combustion engines are purified by catalytic converters that use precious metals (e.g., platinum, palladium, ruthenium) on a silica-alumina honeycomb structure to burn off residual hydrocarbons. Detergents and soaps are made using copper–chromite catalysts. Hydrogenated vegetable fats and oils are produced or purified by nickel and bleaching-clay catalysts. Zeolites and molecular sieves synthesized from silica, alumina, and titania minerals are used commercially to produce chemicals like cumene or paraxylene that are processed further into plastics used in buildings,

cars, and toys. Even the plastic powder for 2-L beverage containers (e.g., soda pop and drinking water) is first purified with a precious-metal-on-carbon catalyst to remove yellow color bodies and to produce a crystal-clear view of the beverage.

MATERIALS

Careful study of the scientific literature on catalysts reveals that most elements in the periodic table have been used effectively in catalysts. For example, uranium was used in a selective ammoxidation catalyst developed by Standard Oil of Ohio (now BP) in the early 1960s. All the metals and nonmetals used in catalysts are derived from minerals, but almost none of them are used directly as recovered. Three exceptions are:

1. Bauxite, used in the Claus process for converting H_2S to sulfur
2. Kieselguhr (diatomaceous earth), used as a support for precious metals in some hydrogenation catalysts
3. Iron oxide (red) mud, used in older ammonia catalysts

Activated carbon and char coal are used as catalyst supports, generally in hydrogenation catalysts.

Generally, the key attribute for the successful application of these materials is their physical form. Catalysis requires contact between the reacting species and the surface of the catalyst. This contact is enhanced when the surface area of the catalyst is high, especially in materials with an open porous structure, where most of the measurable surface area exists on the walls of pores. The pores must have diameters large enough to accommodate free passage of feed and product molecules; because the majority of the surface area is on the walls of pores, however, an increase in pore diameter has a corresponding decrease in surface area. Over the last century, techniques were developed relying on precipitation: Sol-Gel; calcination; and to some extent, gas-to-solid reactions, such as flame spraying, for making useful materials such as catalysts and catalyst supports.

To be effective in various catalytic processes, solid materials must be formed into powders, balls, pills, “noodles,” and so forth. Because catalysts tend to be used for years at a time, the particles must be physically strong and must maintain their integrity under reaction conditions. For example, powders used in FCC processes have an average particle diameter of about $70\text{ }\mu\text{m}$ and must pass stringent attrition tests. This ensures their retention in the unit while they are circulated between reactor and regenerator five to ten times

per hour for months without decrepitating into fine powders that may be lost into the atmosphere as waste.

REFINING CATALYSTS

In 2004, approximately 85 million bpd (barrels per day; about 14 million st/day) of crude oil were produced worldwide. This quantity is reduced through distillation, but most is processed through refinery conversion units (Stell 2003). Conversion may involve a reduction in molecular weight of the distilled feedstock (as in catalytic cracking or hydrocracking), an increase in molecular weight (as in alkylation and polymerization), or a change in the structure of the feedstock without an appreciable change in molecular weight (as in reforming, isomerization, and hydrotreating). In addition to these conversion processes, refiners use catalysts for environmental purposes (SO_x , NO_x , hydrogen sulfide, and CO emission control) and to manufacture on-site hydrogen (water–gas shift and steam reforming) (Magee and Dolbear 1998).

All of these processes use catalysts that are formulated to contain a wide variety of minerals. The minerals contained are rarely used as-is in catalyst formulations; rather they are variably pre-treated chemically or thermally before they are incorporated into the catalyst formulation. An example of a treated mineral product widely used in petroleum catalysis is alumina. In this case, the mineral is bauxite, which consists of aluminum hydroxide and aluminum oxide hydroxide. In their catalytic use, mineral aluminas are converted to active aluminas through the conversion of either gibbsite (gamma aluminum trihydroxide) or boehmite (aluminum oxide hydroxide) to high-surface-area gamma alumina, or through the conversion of bayerite (alpha aluminum trihydroxide) to high-surface-area eta alumina (Satterfield 1980). The crude oil itself is carbonaceous material containing small (parts per million) levels of vanadium, nickel, copper, iron, and other heavy metals.

Tables 1 and 2 present a summary of catalysts and their mineral components used in the major petroleum conversion processes and other related processes. Some of the processes, especially catalytic cracking, are presented with literally dozens of catalysts for the various requirements of individual refiners. These requirements may depend on the type of feedstock being processed, the product demands of a specific market, or the type of conversion units that the refiner uses (Stell 2003). Thus, in Table 1 the catalyst formulations cited are a more or less generalized average of all the catalyst grades manufactured by the suppliers and available to the refiner. To accommodate this generalization, a range has been given, where possible, for the mineral content. This figure is shown in weight percent (wt %) of the catalyst formulation. Only the most widely produced formulations are given. It must be emphasized that the minerals cited are *rarely* used as-is, and the processing used prior to incorporation in the catalyst formulation will be described in the text devoted to each catalyst type.

Specific Refining Processes

More detailed descriptions of the processes presented in the following subsections are found in Magee and Dolbear (1998).

Catalytic Cracking

It can be argued that the catalytic cracking process is the most important technology to come out of the first half of the 20th century. The process allows oil resources to be converted into the most needed products in high yield: gasoline, diesel, and turbine fuels. FCC is the most flexible process in the refinery.

This flexibility results in part from the development of a surprising variety of catalyst types to meet many requirements. Cracking units are large, typically 40,000 to 100,000 bpd, and a typical

unit contains 100 to 300 t of catalyst at any one time, an amount referred to as its “circulating inventory.”

The chief function of the FCC unit (FCCU) is to reduce the molecular weight of the feedstock (distillation range of 650°F to 1,000°F) to make lower-boiling-point transportation and heating fuels and valuable light gases high in olefin content. To accomplish this, a wide variety of catalysts are manufactured and a wide variety of feeds are processed. The catalytic sites are strong acids, chemically equivalent to 90% sulfuric acid in their acidity. Catalysts must have the ability to withstand high temperatures under alternating oxidizing and reducing environments and to continue operation with accumulations of several thousand parts per million of nickel, vanadium, iron, and copper coming from the crude oil. Although typically 60 to 100 µm in diameter, they must have the mechanical strength to survive the physical punishment they endure during routine operation, where any given sample passes through the unit up to 10 times per hour.

Manufacturing the wide variety of catalysts needed uses two very different processes: in situ and incorporation.

The in situ process uses high-purity kaolin as the starting material. It is slurried in water, spray-dried to form microspheres, and calcined at temperatures near 1,800°F to form extremely hard particles 70 µm in diameter. The microspheres are basically an incipient mulite at this point and are catalytically inactive. Since an acidic solid surface is necessary for catalytic cracking, the microspheres are processed further with meta-kaolin and concentrated sodium hydroxide to produce an in situ external and internal porous system containing Type Y zeolite (synthetic faujasite) in its sodium form. Simple ammonium exchanges with the sodium, followed by low-temperature drying, yield the active solid-acid cracking catalyst. Alternate exchanges with mixed rare earth chloride solutions can give a variety of activity and stability levels. Special requirements for gasoline octane enhancement, Ni and V tolerance, and heavy molecule cracking are met through a wide variety of preparative changes.

In the incorporation process, components of the catalyst generally are mixed in a high-shear mixing tank and then spray dried. The resulting microsphere at that point contains a binder (usually silica sol, but sometimes alumina sol), the sodium or exchanged

form of zeolite Y (synthetic faujasite), kaolin, and an activated form of bauxite alumina (generally gamma alumina). (Alternatively, the bauxite may have a mineral phase such as boehmite or gibbsite, which is then converted to gamma alumina during operation in the FCCU or by calcination at the manufacturer.)

Both procedures fill the needs of refiners and are actively employed by three main suppliers: Engelhard Corporation (incorporation and in situ), Albemarle (formerly Akzo Nobel; incorporation), and Grace Davison (incorporation). These three companies account for about 95% of the catalyst market, with the remainder supplied by Catalysts & Chemicals Industries Co., Ltd. (CCIC) and Sinopec Corp.

Catalytic Cracking Additives

In the mid-1970s it was discovered that carbon monoxide could be oxidized completely to CO₂ in the regenerator of the FCCU without being emitted into the atmosphere. This is accomplished by simply adding a very small quantity of platinum-on-alumina powder to the circulating inventory of the cracking catalyst. This gave rise to an entire subclass of fluid catalysts called “cracking catalyst additives.” Now, nearly three decades later, additives are available for gasoline octane enhancement, heavy molecule (bottoms) cracking, gasoline sulfur reduction, SO_x emission control, NO_x emission control, and (originally) CO emission control. A recent survey shows that nine companies are involved in supplying additives to the refining industry. All major FCC catalyst suppliers are involved, but specialty producers such as Intercat Inc. and Ambur Chemical Co., Inc., supply major portions of the market (Stell 2003).

Additives are made to be compatible with the fluid cracking catalyst in use in the FCCU. Therefore, each additive is manufactured in the FCC catalyst size range (~60 µm average particle size) and at approximately the same density (~0.7 g/cc). An additive then transports throughout the reactor with similar fluidization properties as the FCC catalyst. In operation, the additive is added to the FCCU with the principal catalyst, or separately in an amount from 1% to 10% until the desired change in product yield is achieved or until the desired reduction in gaseous emissions is obtained.

As shown in Table 1, additives contain some minerals commonly used in FCC catalysts, but also some not found in FCC catalysts. In bottoms cracking and octane enhancement applications, one can expect to find formulations similar to FCC catalysts because the reactions being catalyzed depend on solid-acid surfaces; the mechanism of octane enhancement, however, requires the presence of a shape-selective zeolite (ZSM-5) rather than faujasite.

SO_x reduction is achieved by reversibly reacting SO₂ and SO₃ onto the catalyst in the oxidizing atmosphere of the catalyst regenerator and carrying the sulfur into the reducing environment of the reactor, where it is converted to H₂S and released into the product vapor stream. This takes place on a solid that is essentially a modification of magnesium aluminate, typically promoted with vanadium and ceria. The overall reactions are complex but have been described in Magee and Mitchell (1993).

NO_x reduction depends on the reduction of NO to nitrogen. Again the reactions are complex, but satisfactory catalysts have been discovered that are alumina based (gamma alumina), promoted with cobalt and lanthanum.

Gasoline sulfur reduction additives convert thiophenes and mercaptans (alkyl sulfides) to hydrogen sulfide, which then can be separated from the gasoline fraction and converted to elemental sulfur in a Claus reactor. Again, an alumina base (as gamma alumina) promoted with zinc oxide is being used.

Although none of the previously described formulations represent a major usage of industrial mineral components, their

importance to the petroleum refiner cannot be overemphasized. Incremental changes in yield structure (potentially achieved with octane, bottoms cracking, and gasoline sulfur-reduction additives) can make a substantial difference in refinery profitability. Also, the proper emission controls for CO, NO_x, and SO_x in this era of environmental uncertainty can mean the difference between compliance and noncompliance with U.S. Environmental Protection Agency (EPA) regulations.

For all these reasons, one can expect the additives segment of the petroleum catalysis industry to grow in both size and diversity.

Reforming

The reforming process produces aromatic compounds from naphthenes (cycloparaffins) and alkanes (paraffins) in the same boiling range as gasoline (100° to 440°F). In the process, both dehydrogenation and cyclization occur. Reforming catalysts contain active metals supported on an alumina carrier (usually high-surface-area gamma alumina or eta alumina, which is treated with chlorides to give an acidic surface). The reactions are performed in a high-pressure atmosphere of hydrogen. Catalysts of this type contain an active metal that functions as a hydrogenation–dehydrogenation catalyst and an acidic component that can induce a carbenium reaction to promote cyclization or cracking. These are called “dual function” catalysts.

A variety of reactor configurations are used in reforming, operated at different reaction severities. Many different formulations optimize catalyst performance under specific conditions. This accounts for use of platinum, rhodium, iridium, or tin as the active metal on the alumina support. In some situations, combinations of two or more of the active metals are used. As stated earlier, quantities of mineral-derived components are not large, but the catalysts themselves play an essential role in the overall quality of the gasoline product. Gasoline-range aromatics from the reformer typically exhibit octane numbers of 110 or greater. Reforming catalysts are expensive but may last in operation for years and can then be either reclaimed or, in some processes, regenerated during the operation (Sinfelt 1997). Refiners often use catalysts under “rental” contracts, with precious metals remaining the property of the manufacturer.

Reforming, and many of the other applications discussed here, use catalysts as solid particles (e.g., 1/16 to 3/8 in. in diameter) in what is known as a “fixed-bed mode.” The catalysts are a heterogeneous type made up of a solid support/carrier that typically is coated with an active metal. The active agent also can be blended directly with the support during the manufacturing or forming process. Catalyst particles are loaded into large vessels or tanks, sometimes in quantities of 100 to 500 t. There is a requirement for both strong physical integrity and high activity–selectivity. Usually these two requirements conflict with one another, and so, through an optimization process, a material having the best of these qualities is produced.

Catalyst supports for fixed-bed mode are found in a variety of forms. Among these are granules, tablets, and extrudates, which are the most commonly used form. These come in a vast number of diameters and specialty shapes. Extrudates are made by combining powders and liquid chemicals into a type of semidry paste. Screw-type auger devices then force the paste through dies with tiny holes, creating the desired shape and size. By analogy, spaghetti and other pasta noodles are prepared in much the same way, but catalyst extrudates are quite a bit shorter (e.g., 1/4 to 3/8 in.). Tablets are formed when a mixture of active component, lubricant, and binder powders are compressed by mechanical force into a cylindrical shape. Vitamin and medicinal pills are also made by a similar tableting process.

Active agents are either coated onto the surface of the catalyst support or combined before the forming technique (e.g., extrusion or tableting). Typically, active agents (as liquid chemicals) are sprayed onto the catalyst support while it is tumbling inside industrial mixing equipment. The coated media is dried to remove moisture, and then is usually heat treated at a high temperature (i.e., 950° to 1,300°F) to drive off any residual nitrates, chlorides, etc., that were used to dissolve the active agent.

Hydrotreating

Hydrotreaters in the refinery remove sulfur or nitrogen from any product molecule or from the process feedstocks themselves. Environmental restrictions on emissions dictate that levels of S and N should be low in products that may be released into the atmosphere. For example, diesel fuels for sale in the United States after July 2006 may contain no more than 15 ppm S; native oils often contain more than 5,000 ppm S. Hydrotreating treats more barrels per day than any other catalytic process in the refinery scheme. Not surprisingly, the quantity and variety of hydrotreating catalysts produced are exceeded only by the FCC catalyst demand.

Four main hydrotreating-catalyst formulations are manufactured, all of which use gamma alumina supports: molybdena on alumina promoted with cobalt; molybdena on alumina promoted with nickel; and, to lesser extent, cobalt- and nickel-promoted tungsten on alumina. Cobalt-promoted catalysts are used primarily for sulfur removal, whereas nickel-promoted catalysts are more effective for nitrogen removal. Tungsten–alumina combinations are used in the most severe operations and are significantly more expensive than molybdena–alumina compositions. The actual active catalysts are MoS₂ and tungsten sulfide (WS₂), which usually are formed by sulfiding the catalyst in the hydrotreating unit before introduction of the feed. The cobalt and nickel promoters generally are believed to be incorporated into the layered sulfides, probably along the crystal edges. The catalysts themselves can be operated effectively for years before replacement or regeneration, but they still require a substantial use of cobalt and nickel and, to a larger extent, molybdenum and tungsten (Table 1).

Hydrotreating is expected to grow as a process, providing a source of new or improved catalyst materials. More than 30 million bpd of refinery feeds or products currently are hydrotreated—by far the largest quantity catalytically treated in the refinery. Topsoe, Clausen, and Massoth (1996) wrote a detailed survey of hydrotreating science and technology.

Hydrocracking

As the name suggests, hydrocracking catalysts are dual-function catalysts that (1) reduce the molecular weight of the feed (cracking) and (2) hydrogenate the products while also removing N and S, a notable environmental advantage. As hydrogen is added, the fuel becomes less dense, so that product liquid volumes may be as much as 20% greater than the feed volumes, a distinct economic advantage in an industry where feed and product are bought and sold on a volume basis.

Heavily contaminated crude oils are primary feedstocks to hydrocrackers; the resulting products are motor fuels and high-quality middle distillates (e.g., jet fuel and diesel). Some refiners also apply hydrocracking to make high-quality lubricating oils and specialty mineral oils for the food and cosmetics industries.

At least a dozen catalyst formulations are in commercial use; Table 1 lists the mineral-related components. Zeolite catalysts find widespread application in this area. A formulation commonly used to produce gasoline-range products of low sulfur content contains approximately 0.5% palladium, 35% exchanged and thermally

treated zeolite Y (synthetic faujasite), and 65% alumina (gamma alumina type, derived from gibbsite or boehmite). When the product emphasis is directed toward high-quality diesel-range products, a widely used formulation contains the same zeolite Y content (35 wt %), but in stead of palladium, the hydrogenation function is supplied by 20% WS_2 promoted with nickel (~4% as NiO). The balance of the formulation again is supplied by gamma alumina. Formulations containing MoS_2 for the hydrogenation function and combinations of silica-alumina also are widely used in the hydrocracking process.

Catalysts are supplied under license by UOP LLC, Chevron USA Inc., ExxonMobil Corporation, and IFP Group Technologies, and principal manufacturers Criterion Catalysts and Technologies LP, Albemarle, and Grace Davison. Works by Magee and Dolbear (1998) give more information on the hydrocracking process and catalysts.

Zeolites are used as catalysts for hydrocracking and a variety of other industrial chemical processes. Zeolites are composed predominantly of silica and alumina. Other elements such as gallium, germanium, cobalt, and nickel and the compounds titania and alumina phosphate can be incorporated into the zeolite structure as well. If these other substances are present, the net material is called a *molecular sieve*. Zeolites originally were discovered as natural ore deposits. Minerals such as clinoptilolite and chabazite are mined in large megaton quantities for use in ion exchange, in water softening, and in the removal of radioactive isotopes from wastewater from nuclear power plants.

Essentially all zeolites and molecular sieves used for catalysis are synthesized commercially. Typically, processing equipment consists of stirred-tank reactors placed under high-temperature and pressure conditions. Usually, liquid silica and alumina chemicals are combined with organic templates (e.g., amines, tetra-ethyl ammonium hydroxide) and mixed for long periods ranging from 1 to as long as 6 or more days. During this time a crystallization process takes place that will form the material into a specific molecular shape and particle size. The particles are quite small, typically 13 μm . Under the microscope, they might look like thin rods, flat platelets, cubes, or even rose petals. A particular type of zeolite or molecular sieve is synthesized by following a manufacturing recipe that specifies raw materials, mixing conditions, temperature, pressure, and length of time.

The molecular structure of these materials also is carefully controlled during crystallization. Internally, zeolites consist of a series of microscopic channels or tunnels within walls that are 6-sided, 8-sided, 12-sided, or more. The channels comprise alumina, silica, titania, or other chemical molecules that form a series of cross-linked, reticulated chambers resembling a honeycomb. This structure allows for the passage (or diffusion) of certain chemical functional groups to the catalytic sites while preventing others from entering. Specific chemical reactions will occur on these active sites within the honeycomb-like channels. Conversely, products from the reactions will either diffuse out or be prevented from leaving. Both high activity and selectivity are achieved with zeolite or molecular sieve catalysts, and they can be tailored for high performance for a given chemical reaction.

Alkylation

Reactants in the alkylation process are isobutane and olefins (usually pentenes, butenes, and propylene). Products are valuable, highly isomeric, gasoline-range hydrocarbons of high research and motor octane. Such stocks are also free of sulfur except when produced by units that do an ineffective job of removing sulfuric acid aerosols from the products.

The reactions are catalyzed by strong acids; usually concentrated sulfuric and hydrofluoric acids are used. Process conditions are mild: temperatures at $\sim 10^\circ$ to 100°F , and pressures at 50 to 100 psig. Because of environmental concerns there is a major effort to replace these acids with more environmentally friendly materials. This has resulted in the commercialization of so-called solid alkylation catalysts (SACs). To date, the composition of the catalysts used has remained more or less proprietary, but the following formulations are known: trifluoromethane sulfonic acid on a porous support (Haldor Topsoe A/S); a promoted alumina-zirconium halide (Catalytica Energy Systems, Inc.); an antimony pentafluoride on acid-washed silica (Chevron USA Inc.); and a solid catalyst that resembles traditional hydrocarbon conversion catalysts (UOP LLC).

Although mineral-derived catalyst use is relatively small in tonnage and dollars (catalyst sales per year are <\$90 million), the market will remain strong for the foreseeable future. This is because high-octane gasoline products are not only environmentally friendly but are also excellent performance motor fuels.

Tarry by-products tend to form in the sulfuric acid process, and fresh sulfuric acid is added routinely to replace that which is removed for regeneration. Regeneration is accomplished in sulfuric acid furnaces, making the overall consumption of new sulfuric acid negligible.

Isomerization

Isomerization processes convert normal (straight-chain) pentanes and hexanes, naphthenes (cyclohexane), and benzene into a mixture of highly branched isopentanes and higher molecular weight isomers. They use a dual function catalyst capable of catalyzing hydrogenation (an active transition metal) and carbenium ion (solid acid catalyzed) reactions. The reaction takes place in a high-pressure atmosphere of hydrogen. Products, as in alkylation, are valuable gasoline-range materials.

Acid activity is supplied by either a zeolite (exchanged and thermally modified zeolite Y [synthetic faujasite]) or chlorided gamma alumina, and the hydrogenation function is platinum. Although the amount of isomerization on catalyst produced is relatively small, the product value is high. The process is used where much less valuable normal pentanes and hexanes represent a significant quantity of materials in this boiling range. Also, as shown in Table 1, the amount and type of mineral-derived catalyst components bear a strong resemblance to many of the formulations used in higher catalyst consumption processes.

Polymerization

The polymerization process has been widely used for more than 50 years to produce highly branched, high-octane, gasoline-range olefins from light olefins (mainly propylene and butylene). One of the earliest catalyst formulations consisted of a phosphoric-acid-activated mineral, kieselguhr, which is a form of diatomaceous earth. More recently, a polymerization process developed by ExxonMobil Corporation was used to produce either gasoline-range aromatics or distillates depending on the temperature or pressure of the reactor. In this case, the catalyst contains the molecular sieve ZSM-5 bound with gamma alumina. Although neither process is used very much when compared to the other refinery processes described, the polymerization process provides valuable catalyst products and is used when olefin feedstocks are readily available.

Petroleum Refining Catalysts—Related Refinery Processes

Two processes are necessary for the overall well-being and upkeep of a refinery: (1) hydrogen sulfide removal from all refinery streams

and (2) production of hydrogen gas using the steam-reforming and water–gas shift processes. The two processes are widely used and have high-volume catalyst utilization, but they are not directly connected to making refinery products. Catalyst formulations bear a marked resemblance to many other refining catalysts and are shown in Table 2. The catalyst formulations listed represent an estimated average for each.

Hydrogen Sulfide Removal—the Claus Process

The Claus process (Wagner and Nehb 1997) catalyzes the oxidative conversion of hydrogen sulfide to elemental sulfur using granular bauxite as the catalyst. Until the mid-1960s it was used worldwide. Today the process is used in hundreds of plants with sulfur capacities up to 2,000 tpd of activated alumina- or titania-based catalysts. The most desirable properties of these catalysts are high surface area (200 to 400 m²/g), pore volumes from 0.4 to 1.0 cc/g, and large pore diameters (~75 µm). Cobalt and molybdenum are used as promoters in a number of Claus catalysts. With the current emphasis on environmental issues, the Claus process and catalysts keep refinery operations in compliance by mitigating hydrogen sulfide streams regardless of the source.

Hydrogen Production—Steam Reforming

Although catalytic naphtha reforming produces hydrogen gas in large quantities as well as gasoline-range aromatics, most refiners also rely on steam reforming (Magee and Dolbear 1998) to supply their many hydrogen needs. Steam reforming plants actually rely on several catalytic steps. Most prominent of these is the reaction of steam with light hydrocarbons to make a mixture of hydrogen and carbon monoxide, and then the conversion of this mixture to hydrogen. The process also uses a hydrotreating step to remove any sulfur from the hydrocarbon feed; for adsorption of product H₂S onto zinc oxide; to remove by-product CO₂ from the hydrogen in one of several noncatalytic steps; and for the catalytic reaction of trace CO₂ and hydrogen to make methane as a protection for downstream catalysts.

Metallic nickel supported on alumina (corundum) or calcium aluminate catalyzes the reaction of steam at high temperatures (typically >1,500°F) with a low-molecular-weight hydrocarbon (usually methane) to form hydrogen and carbon monoxide (steam reforming). Nickel content in these catalysts is very high (~40+ wt %), and the process must be operated at very low sulfur levels because of the extreme susceptibility of nickel to sulfur poisoning.

In the water–gas shift reaction, hydrogen and carbon dioxide are produced from the reaction of carbon monoxide and steam using several different catalyst types. So-called high-temperature shift (HTS) reactions (600° to 1,020°F) are catalyzed by magnetite (Fe₃O₄) containing minor amounts of chromia, whereas low-temperature shift (LTS) reactions are catalyzed by copper metal paired with zinc oxide and alumina.

As previously mentioned, both water–gas shift and steam reforming are important processes that help fill the refiner's internal hydrogen needs. Data shown in Table 2 suggest that the quantities of catalysts used for both steam reforming and the related water–gas shift process are not large, but nevertheless the refiner is highly dependent on them for much-needed hydrogen.

CHEMICAL CATALYSTS

An immense variety of catalytic materials is used in manufacturing chemical intermediates and products. Most of these catalysts are low-volume materials, especially when compared with refining catalysts; many of them have operating lives measured in years rather than months. Detailed information about them may be difficult to

obtain because compositions and applications are proprietary to the companies that develop and use them.

This section describes several of these catalysts in general to give the reader a feeling for their variety and importance.

Ethylene Oxide

One of the major uses for ethylene is in making ethylene oxide (EO), a product measured on a scale in tons and used mostly in making ethylene glycol, one of the two intermediates for polyesters. The classic catalyst for this application is silver supported on silica gel. Continuing research has led to many small improvements in this basic formulation to improve selectivity, which is defined here as the oxidation yield to EO rather than CO₂.

Saturated Fats

Natural fats and oils are selectively hydrogenated to make products with higher melting points and other desired properties. Catalysts for this hydrogenation typically are based on nickel, supported on silica, kieselguhr, or some other porous solid, or in the form of Raney nickel alloys. Raney nickel contains nickel and aluminum and is activated by hot water or steam to convert some of the aluminum to hydrous oxides.

Ammonia

Development of the synthetic-iron ammonia catalysts in the early decades of the 20th century led to widespread use of nitrogen fertilizers, which have accelerated the production of food worldwide. A variety of processes were developed around the ammonia, allowing the manufacture of inexpensive nitric acid, ammonium nitrate, urea, and other nitrogen-based chemicals. The key invention in the ammonia catalyst, by Fritz Haber and Karl Bosch, was the addition of small amounts of potassium and aluminum oxides as promoters to the iron oxide catalyst. The iron oxide itself is not the active catalyst, but is converted in the reactor to active metallic iron by reduction with hydrogen. The iron oxide usually is prepared by precipitation of a hydroxide or hydrous oxide, which is dried, calcined, and formed into strong particles. Some commercial catalysts have been made directly from oxide minerals.

The ammonia process also incorporates a long series of additional catalytic steps. The process typically starts with natural gas, which is first desulfurized and then reacted with steam to form a mixture of CO and H₂. This mixture is then passed over a series of water–gas shift catalysts to convert the CO to more hydrogen. Each of these steps is catalytic, using various catalysts made with cobalt, molybdenum, nickel, copper, and chromium. There are also sulfur and CO₂ removal steps. In the sulfur removal step, H₂S formed during desulfurization is adsorbed onto ZnS. The CO₂ removal step uses any of several adsorption technologies; trace CO₂ also may be removed by catalytic hydrogenation to methane.

Selective Oxidation

Many chemical products are made by selective oxidation of some intermediate material. Catalysts for these oxidations often are based on vanadium oxide and often are promoted with lesser amounts of other oxides such as bismuth. Other catalysts used in selective oxidation are those based on manganese, chromium, zirconium, niobium, molybdenum, and even uranium; many catalysts are well-defined mixed oxides such as copper chromite or bismuth molybdate. Research has shown that such materials generally operate by supplying oxygen from the oxide matrix, which is then replenished by reaction with oxygen fed with the organic starting materials. Selectivity often is controlled by precipitating the precursor hydroxides in such a way that specific crystalline faces are

avored; much of this technology is proprietary to the companies that developed these catalysts.

Terephthalic Acid

Terephthalic acid is a high-volume intermediate used for the manufacture of polyesters. It is made by selective oxidation of very pure para-xylene with air or oxygen. The classic process for this conversion, the Midcentury Process, uses manganese or cobalt salts dissolved in glacial acetic acid. Bromine is used as a co-catalyst. Many variants and improvements have been made to this process in the nearly 50 years since its introduction. These technologies, coupled with the proper product isolation steps, result in a polymer intermediate material with levels of total impurities less than 25 ppm, essentially pharmaceutically pure products.

Automotive Exhaust Control

The introduction of catalysts to reduce carbon monoxide, hydrocarbons, and nitrogen oxides dramatically improved urban air quality. The original catalysts were introduced in the 1970s, and a series of dramatic improvements over the ensuing 30 years have significantly reduced the pollutants emitted by the modern automobile. Modern catalysts rely on a combination of precious metals, with platinum or palladium mixed with iridium, rhodium, and others. These catalysts are used in the form of thin coatings on monolithic honeycomb materials based on high-temperature ceramics.

SUMMARY

A survey of compositions for petroleum refining and chemical process catalysts presented in this chapter shows an extremely wide range of mineral-derived components currently in use. Noble metals, rare earths, transition metals, acids, zeolites, silicas, and aluminas are part of the myriad systems available to petroleum refiners and chemical manufacturers. Characteristic of most catalyst compositions available is the presence of bauxite-derived alumina. Alumina invariably is converted to an active phase—gamma or eta—and is an essential ingredient of many petroleum and chemical cata-

lysts. Many of the conversion processes call for strong acids that require some degree of uniform structure. In these cases—catalytic cracking is a prime example—zeolites such as Type Y (synthetic faujasite) are needed. Cobalt, nickel, molybdenum, and tungsten supported on alumina are the principal ingredients in the most used process in the refinery—hydrotreating. Noble metals and zeolites are used for hydrocracking with noble metals supported on modified aluminas handling catalytic reforming.

Although the quantity of mineral-derived catalyst components may not be large compared to other industrial uses, it is apparent that extraordinary contributions come from minerals used in petroleum refining and chemical catalysts.

Adobe and Earthen Construction

George S. Austin and David A. Holmes

INTRODUCTION

Soil is the ultimate sustainable building material, meaning that it has little effect on the environment, and that building with it expends little or none of the earth's finite resources, such as fossil fuels. Its "embodied costs," which means the cost to individuals and society overall in its creation, storage, distribution, use, and maintenance, are very low. The cost of housing is a critical factor for the future survival and well-being of the earth's population.

Mud or earthen material is one of the oldest building materials used by humans. Today, close to 40% of the world's population lives in earthen buildings. If the world's population doubles by 2060 as projected, that proportion probably will stay about the same, greatly increasing the number of earthen-construction dwellers. Not all of these people are members of primitive societies or live in developing countries. Some European, African, Asian, and North and South American countries, in addition to Australia, are home to a significant number of such structures. In the United States, the American Southwest in particular is known for earthen construction (Austin 1994).

Some of the earliest remains of adobe brick were discovered in the ruins of Neolithic farming villages in Mesopotamia dating as far back as 7,000 BCE (before the Common Era; Steen 1972). The Spanish conquest of the New World spread the use of wooden molds used to prepare a standard adobe brick. The word *adobe* is Spanish for "mud brick," or for the clay soil from which the brick is made. The term has its roots in Egyptian hieroglyphs (Lumpkins 1977). The Arabic word for mud brick is *ah-tob* or *al-tob* (sun-dried brick), which traveled with the Arab migration westward from the Middle East and Egypt to Spain, as the root word of adobe. Today adobe is used in the United States and Latin America to describe not only the sun-dried adobe brick but also puddled adobe structures, mud-plastered logs or branches (jacal or wattle-and-daub), pressed-earth blocks, and rammed-earth walls, or *pisé* (Ferm 1985; Smith and Austin 1996). The rest of the world uses variations of the terms "earth or earthen construction" to describe all types of construction using mud or soil raw materials.

Modern mud construction is used in many countries around the world. In North America, the southwestern states from Texas to California are best known for earthen construction, and New Mexico has the dominant reputation for adobe brick construction. Indeed, in New Mexico, the Santa Fe style (Figure 1) has made adobe not only acceptable but preferred.

RAW MATERIALS

Geologic Settings

Virtually all earthen or adobe materials are recovered from soils or soft alluvial sediments on the surface of the earth. Although medium- to coarse-sized sand is the most important structural component, clay is the most important fine, binding component. Gravel-size particles add strength to earthen walls but are generally kept to less than 10% as they tend to pop out. Silt and fine sand contribute the least strength to earthen structures and act more as filler material. The best earthen construction raw materials are generally Recent stream or river sediments or residual soils containing a wide range of particle sizes. The two great original areas of earthen construction in ancient Egypt and Mesopotamia depended on the sediments of the broad Nile and Tigris/Euphrates River valleys, respectively, as raw materials. Soils used by current and past adobe producers in the Americas are mostly sandy loam (50% clay and silt), although clayey silts are used in some areas (Coffman et al. 1990). In New Mexico, the best adobe soils are those developed on stream deposits, particularly Recent terrace deposits and loosely compacted Tertiary formations, such as the Santa Fe Group in the Rio Grande Valley. Soils of windblown origin are not commonly suitable for earthen

construction unless other surface materials are added. Wind action concentrates surface sediments by particle size. Coarse sand and light gravel are generally missing altogether, and the clay fraction was blown much farther away at the time of deposition. Some modern adobe producers use a mixture of materials from the screened fines of aggregate operations and mud dredged from irrigation ditches in river valleys, combined with varying amounts of sand, to produce proper blends.

Mineralogy

X-ray diffraction analyses of whole-rock samples show that the major constituents of New Mexican adobe soils are quartz and feldspar, with lesser amounts (in decreasing order of abundance) of calcite, clay minerals, and gypsum. The quartz, feldspar, most of the clay minerals, and some calcite are derived from the mechanical/chemical breakdown of older rocks. Some clay minerals, much of the calcite, and all the gypsum are precipitated from evaporating water.

Clay Properties

Clay-size particles, although the smallest in percentage of size in earthen construction material from New Mexico, are the most compositionally variable in commercial adobe soils. Clay minerals are dominant, but nonclay minerals also are present. In this size fraction, clay mineral groups consist of about equal parts of expandable clay minerals (smectite and mixed-layer illite/smectite, or I/S) and nonexpandable clay minerals (kaolinite, illite, and chlorite), with minor constituents of quartz, calcite, and feldspar (Smith and Austin 1989, 1996; Austin 1990). The smectite is universally calcium-rich, and the I/S is disordered, randomly interstratified smectite and illite. Only 2 of the 42 samples taken as part of the study by Smith and Austin (1989) contained chlorite; vermiculite, sepiolite, and palygorskite were not found. Although commonly found in minor amounts, clay-sized calcite was present in nearly every adobe soil sample.

Expandable clay minerals tend to be more “sticky” than nonexpandable varieties and thus are more effective in binding silt and sand particles together. Expandable clay minerals also form colloidal suspensions with water. As a result, moisture, whether from rainfall or groundwater, has its greatest effect on adobe soils with large proportions of smectite and I/S.

For past and present adobe producers in New Mexico, expandable clay minerals have sometimes proved problematic. Cracking of adobe bricks while drying is most probably caused by a large proportion of smectite and I/S in the adobe soil; soils with higher clay content but relatively lower smectite and I/S content are less likely to crack. Although cracking is extreme on windy days when the shrinking of clay occurs more rapidly, drying slowly over many calm days allows multiple layers of finely crystalline calcite (and some gypsum) to form on a clay-size scale, strengthening the bricks and preventing cracks. If the adobe bricks do not contain too much clay material and are properly cured, the resulting adobe wall can resist torrential late-summer rains for many years.

Chemical Properties

Soils in the arid New Mexican climate are typically alkaline. Groundwater near the Rio Grande Valley, where most of the adobe brick in New Mexico is produced, is generally hard to extremely hard, containing total dissolved solids (TDS) ranging from about one hundred to several thousand parts per million (Wilkins 1986; Anderholm 1987; Austin 1994). Soluble salts, notably calcium carbonate and calcium sulfate, precipitate as this water evaporates. At the surface of seasonal marshy areas of the state, white crusts of

Source: Austin 1990.

Figure 2. Summary of leaching analysis of 25 commercial New Mexico adobe soils

these salts commonly appear during drier times of the year. The desert surfaces are stabilized by precipitation of calcium carbonate from groundwater, initially producing calcium-rich soils, followed by impermeable pedogenic calcite layers, called *caliche*, just above the groundwater table (Gile, Hawley, and Grossman 1981).

Adobe walls in New Mexico are remarkably durable in the dry desert climate. With proper care, walls may last for hundreds of years. Great care is taken to keep the interior walls dry. In Native American pueblos, the inhabitants re-cover exterior adobe walls with a natural plaster each year as part of community service. The natural plaster has about the same mineral and chemical composition as the walls themselves but is slightly finer grained. It is expected to erode off slowly during the year and is then replaced during the next year's replastering. The slow weathering of the plaster apparently results from calcite and gypsum precipitation from water used in mixing the plaster. This precipitation forms a caliche-like bond between grains as the mud plaster slowly dries.

Leaching tests with EDTA (ethylenedinitrilotetraacetic acid) on 25 commercial New Mexican adobe soils (Figure 2) suggest that commercial soils contain an average of about 90% insoluble and 10% soluble material; the latter is dominantly calcite with some gypsum (Austin 1990). In that study, the soluble material ranged from 36 wt % to essentially zero. Adobe soils with the smallest amount of soluble material were also the highest in sand and larger-size particles.

Physical Properties

Particle-Size Distribution. The common statement by New Mexican adobe producers is that their soil mix is usually one half sand and one half clay or fines (silt and clay), although commercial adobe soils range from 85 to 99 wt % nonclay-size particles (Smith and Austin 1989, 1996). Tests of commercially produced adobe show that the soil material contains 27 to 89 wt % sand-and-larger grain size, 8 to 68 wt % silt-size grains, and 1 to 15 wt % clay-size grains (Figure 3). The average grain-size composition was 67 wt % sand and larger, 27 wt % silt, and 6 wt % clay. The wide variation of

particle sizes, particularly in the sand-and-larger- and silt-size grains, affects the penetration of paint or stabilizer sprayed or painted on walls. The smaller the average grain size, the more surface area is involved, and the more preservative is needed to create an impermeable layer to a given depth in the wall. Adobe walls with high clay- or silt-size content would need the largest amount of preservative. An abundance of clay-size particles in adobe soils causes excessive cracks as blocks dry in an adobe yard. To combat this, producers add straw, additional sand, or both, to the mud mixture.

In New Mexico, large-scale commercial adobe producers use adobe soils with less clay-size material than do small-scale commercial and noncommercial adobe producers. Some of the former use soils as low as about 1 wt % clay, whereas many of the latter use soils between 8 and 15 wt % (Smith and Austin 1989, 1996). In part, this is because large-scale commercial adobe producers use stabilizers that not only protect blocks from rain damage but aid in consolidation of the drying soil mix as well.

Thermal Properties

Traditionally, materials are evaluated for the thermal properties based on measurements known as *R-values* and *U-factors*. An indicator of the ability of a wall to insulate effectively, the *R-value* is calculated by dividing the thickness of the wall by the wall's thermal conductivity (the amount of heat per unit area in a given time), flowing from the hotter side to the cooler side of the wall. The units for *R-value* are per square meter/degrees Kelvin/hour/watt (square foot/degrees Fahrenheit/hour/British thermal unit). The inverse of the *R-value*, the *U-factor* reflects the rate at which heat is conducted through a material. The total *R-value* may be calculated for a given wall by adding up the values of the individual components of a wall structure, including all insulation, interior sheathing, framing, airspace resistance, and masonry. Adobe walls have very low *R-values* because they commonly consist of 26-cm (10-in.) or 36-cm (14-in.) blocks covered with a thin stucco on the outside and thin gypsum plaster on the inside.

R-values and *U-factors* do not tell the full story in determining what is a high-quality, thermally efficient wall (Fine 1976). Both these values reflect the rate at which heat passes through a wall only after the steady state of heat flow (the constant rate of heat energy

passing uninterrupted from one side of the wall to the other) has been achieved. What is not considered, although of critical importance in masonry-mass walls such as adobe, is the heat storage capacity of the wall, which determines the length of time that passes before a steady state of heat flow is achieved. The higher the heat storage capacity of the wall, the longer it will take for heat flow to reach a steady state. In real situations external temperatures, in particular, change constantly, so that a true steady-state condition is rarely achieved. Because diurnal changes in the arid Southwest are typically 15° to 28° C (27° to 50° F), a "fly-wheel effect" (in this case, the damping of interior temperature fluctuations resulting from the massive adobe construction) will keep daytime temperatures of adobe buildings cool in the summer and warm in the winter.

Resistance of Sound. Thick massive walls of adobe are well-known absorbers of sound, making these homes remarkably quiet. Windows in older adobe buildings are normally small, adding further to the sound deadening. Newer solar adobe homes take advantage of the many sunny days in arid climates with larger windows that are thermally designed, but also retain much of the sound-deadening characteristics of adobe dwellings.

Other Physical Properties. Other physical properties that make adobe construction advantageous are its water resistance, nonflammable and termite-proof character, and energy efficiency. The sun-dried method of production, rather than the use of high heat to produce masonry brick or cement, contributes to the energy efficiency. Wright (1978) stated that it takes more than 300 times as much energy to produce a commercial concrete block than a sun-dried adobe block of the same volume.

An unusual test on adobe in Nicaragua determined that adobes were resistant to penetration by bullets (Lola 1981). Five shots from a machine gun at an adobe wall at 20-m (61-ft) distance penetrated only 4 to 5 cm (1.6 to 2.0 in.).

INDUSTRY STRUCTURE

Traditional/Old World Sector

Earthen construction, principally adobe bricks, evolved throughout Asia, the Middle East, Africa, and parts of Europe over millennia. Civilizations gradually developed their unique sources of materials and architecture for residential, agricultural, and commercial construction. Building materials and techniques, however, stayed ubiquitously simple, relying on straight walls, simple infill foundations, and too often earthen materials for roofs or multistory structures. The greatest threat to traditional earthen construction is its vulnerability to massive earthquakes, which can result in death and destruction.

Contemporary Construction Sector

In the United States, most adobe artisans come from generations of *adoberos* (adobe makers) who learned their techniques from family traditions locally or in Latin America. The recent heavy wave of migration from Mexico and other Central American countries has brought a large number of workers knowledgeable in adobe construction into the United States. In addition, contractors hiring *adoberos* now commonly recruit workers, as they are needed, from Mexico. Local trade associations, minor academic attention, and a great deal of Internet communication have kept interest in adobe technology alive. Some educational institutions in the Southwest offer formal or noncredit courses in adobe construction. In association with the International Institute for Conservation of Historic and Artistic Works, the Getty Conservation Institute (GCI) of Los Angeles, California, directs attention to the preservation of adobe construction, particularly in the American Southwest. Creation of the Adobe Association of the Southwest is a recent attempt to organize adobe contractors,

Figure 4. After 2 to 3 days of drying time, adobe is released from a 10-brick ladder form at a commercial adobe yard in New Mexico. The adobe is trimmed by hand, turned on edge, and dried for an additional 2 weeks. Blocks then are stacked in the yard ready for sale.

researchers, architects, and students to promote the adobe industry. Older industry groups, such as the El Paso Solar Energy Association, have active programs promoting solar and alternative energy research along with Southwest trends in adobe architecture and design.

International Research Centers

In the interests of improving earthen architecture, a number of international research and academic study groups sprang up during the 20th century. These groups were principally aligned with United Nations relief groups in Europe, but came to show more interest in the North American market. The University of New Mexico's Department of Architecture has offered courses in earthen architecture in both Spanish and English for more than 2 decades. Other branches of the university have been leaders in advancing adobe studies for U.S. applications. Smaller organizations such as Southwest Solar Adobe (SWSA) function today as commercial or educational groups that spread knowledge regionally to the construction industry and interested builders. The International Centre for Earth Construction (CRATerre-EAG, typically abbreviated to "CRATerre"), affiliated with the Ecole d'Architecture in Grenoble, France, trains students in earthen architecture and construction and sponsors conferences and research on earthen technology. CRATerre also contracts with government agencies, particularly in developing countries, to train students and build large housing projects on site. Another typical international research project trained experts at the Regional Seismology Center for South America (CERESIS; El Centro Regional de Sismología para América del Sur) in assessing different methods for strengthening existing earthen homes. The project involved 6 years of research and was funded by the German Cooperation for Development Programme (Deutsche Gesellschaft für Technische Zusammenarbeit GmbH [G TZ]). Considerable progress has been made using structural steel, wire mesh, and selective roof strengthening to reduce deaths related to earthquake destruction. The International Center for the Preservation and the Restoration of Cultural Property (ICCROM; *Centre international d'études pour la conservation et la restauration des biens culturels*) focuses worldwide attention on adobe by holding international meetings on the preservation of earthen construction.

TECHNOLOGY

Several varieties and sizes of earthen brick are produced throughout the American Southwest, including traditional adobe, semistabilized and stabilized adobe, New Mexican *terrones* (cut-soad brick), *quemados* (burnt adobe), and machine-pressed-earth block; in addition, rammed-earth walls are constructed without brick (McHenry 1984; Smith and Austin 1989, 1996). The two major types of adobe brick currently produced in New Mexico are the traditional adobe brick and the semistabilized adobe brick.

Production Techniques

Traditional (Untreated) Adobe Bricks

Often called *untreated* or *sun-dried* adobe brick, traditional adobe is made with soil composed of sand with some larger particles, and of silt and clay (Figure 4). Straw is sometimes added for strength and to prevent excessive cracking during drying. The moistened soil mixture commonly is packed into a brick-like mold, released, and allowed to dry and cure for several weeks before use.

Stabilized Adobe Bricks

The New Mexico Building Code defines fully stabilized adobe brick as water-resistant and made of soil with certain admixtures that limit the brick's 7-day water absorption to less than 4 wt %. A fully stabilized adobe brick usually is made with 6 to 12 wt % of asphalt emulsion (California Research Corporation 1963; Scheuch and Busch 1988). Exterior walls constructed with stabilized mud mortar and brick require no additional protection and can be left exposed without stucco. The production of fully stabilized adobe brick is very low because most walls are stuccoed with water-resistant plaster, and the additional waterproofing agent adds extra cost.

Semistabilized Adobe Bricks

Semistabilized adobe brick was developed by major adobe producers in New Mexico and is classified as a water-resistant brick because of the addition of 3 to 5 wt % of stabilizer or water-proofing agent (California Research Corporation 1963; Scheuch and Busch 1988). The stabilizer protects the brick from rainstorm damage during the curing process. Asphalt emulsion is the primary stabilizer because of the ease of use and the low cost, but 5 to 10 wt % portland cement produces the same result. Semistabilized adobe is made the same way as traditional adobe, except the stabilizer is mixed into the adobe soil prior to packing it into a form.

Pressed-Earth Blocks

Pressed-earth blocks currently make up a small portion of earth brick used in New Mexico (Smith and Austin 1989, 1996). Although the CINVA-Ram hand-operated press, developed by a Chilean engineer in the 1950s, has been used in New Mexico, most pressed-earth blocks in the state are made by gasoline- or diesel-powered machines (Figure 5). Several have been designed and used in the past in New Mexico to press the adobe soil mixture into a form, minimizing the amount of time required between forming the block and placing it into the wall. Portland cement or asphalt emulsion has been used to partly or fully stabilize pressed-earth blocks. Most producers are small volume and/or part-time, or noncommercial.

Rammed-Earth Walls. Rammed-earth homes commonly have much thicker walls than most other earthen dwellings, up to 0.9 m (3 ft) thick. Wooden or metal concrete-type forms are put in place on stone or concrete footings, and layers of moistened soil (15 to 20 cm [6 to 8 in.] thick) are deposited between the walls of the forms. Hand or hydraulic tampers are used to pound the soil into the shape of the form, compacting and reducing the volume of

the mixture by 25% to 30% (McHenry 1984; Middleton 1987). Once the layers of tamped soil reach the desired height, the forms are removed and the wall is allowed to dry (Figure 6). Portland cement is the common stabilizer used. Producers say rammed-earth walls continue to harden, or cure, during the first year after construction. From 2002 to 2005, there were approximately 28 buildings constructed by New Mexico's five rammed-earth construction firms, with 10 built during the spring and summer of 2005.

Specifications

Specifications for adobe or mud construction are not widely used in the United States. The state with the most adobe construction, New Mexico, probably has the most complete approach. The New Mexico code for unburned mud construction is Section 2412 of the New Mexico Building Code. A summary of the most significant rules governing adobe blocks follows (the code uses standard units rather than metric units):

- Compressive strength: The units shall have an average compressive strength of 300 lb/in² when tested.
- Modulus of rupture: The units shall have a 50 lb/in² in modulus of rupture when tested according to the specified procedures.
- Moisture content: The moisture content of untreated units shall be 4%.
- Adsorption: A dried cube cut from a sample shall adsorb 4% moisture by weight when placed upon a constantly water-saturated porous surface for 7 days. An adobe unit that meets this specification shall be considered stabilized.
- Shrinkage cracks: No unit shall contain more than three shrinkage cracks, and no shrinkage crack shall exceed 2 in. in length or 1/8 in. width.

Architectural Advances

Major advances are being made in architectural improvements, principally in the rammed-earth and cast-earth sectors in Australia and Texas. Although the Santa Fe style of adobe design is still the most popular in the Southwest, new design changes are gaining support for using earthen construction in multistory buildings, high-ceiling homes and buildings, and for novel approaches with large glass surfaces, passive solar additions, and functional flooring materials such as tiles and cut stone. In Australia, new architectural designs incorporate brick and concrete work as well as wood ceiling beams and internal structural features such as staircases, all in conjunction with the earthen portion. This not only allows greater beauty in the building, but also contributes to greater building strength from a seismic point of view.

Construction Technique Advances

New construction techniques will produce stronger adobe walls in the future, including (1) the use of rebar and steel wire mesh in adobe walls, (2) building walls that taper from wide at the base to thinner at the top, and (3) experimental additions of new starches and resins to adobe mixes to achieve stabilization with less additive materials. Although traditional adobe-making and building methods will still prevail in remote rural areas, urban areas offer more variety in artisan skills and construction materials that may result in new building techniques.

Research on Product Strength and Longevity

Project TERRA is a research umbrella group formed by CRATerre, GCI, ICCROM, and several other international earthen study organizations, known as the TERRA Partners, to develop worldwide

conservation of earthen architectural heritage. This research effort is also developing new information on ways to improve the strength and longevity of future earthen buildings. On May 14, 2000, the TERRA Partners, in cooperation with the English Heritage group, hosted a meeting in Torquay, England, to begin compiling world knowledge on earthen construction and its restoration, and to establish research priorities for the partners. This was the first international attempt to unravel the physical and chemical attributes of adobe and earthen construction on a very high scientific level. In the meeting, the following themes emerged for channeling future studies most effectively:

- Classification, binding, and unbinding
- Nonstructural decay or evolution
- Structural decay
- Chemical interventions
- Physical interventions
- Continued use

USE AND DISTRIBUTION

United States

Examples of early mud construction are present in many parts of the United States. Perhaps the most famous is the still-occupied, 1,000-year-old Taos Pueblo in New Mexico (Figure 7). Large earthen mounds built by North American aboriginal people, known as mound builders, are present in many parts of the eastern United States as well (Emerson and Woods 1990). The common building method in these pre-Columbian structures was puddled-clay or clay-lump construction, which preceded the adobe mold introduced by the Spanish in the 16th century. Similar construction was used in several sections of the country into the 19th century, as in western New York state (Dassler 1990). During the same period, sod was the principal building material of many immigrants on the treeless Great Plains. As modes of transportation broadened and the cost of moving building materials fell, earthen construction declined in most areas of the country.

An earlier improvement in adobe construction occurred in the 1880s when the railroads reached New Mexico. Local inhabitants soon learned how sloped roofs, covered by corrugated iron sheets brought from the east, were far more effective than the flat, dirt-covered roofs used prior to that time. Modern improvements, such as the use of soil stabilizers, further improved earth blocks' ability to withstand moisture damage.

The American Southwest has long had a love affair with adobe, and the landscapes of Arizona, California, New Mexico, and Texas contain many examples of enduring adobe homes. Old military forts, churches, and commercial buildings also attest to its popularity. New Mexico, both historically and today, is the largest domestic producer and user of adobes. During the past several decades, 3 to 4 million adobe bricks and pressed-earth blocks have been produced in New Mexico each year by as many as 50 commercial manufacturers (Smith and Austin 1989, 1996).

More than 59,000 adobe buildings, representing one third of the adobe dwellings in the United States, are in New Mexico (Gerbrandt and May 1986). Although less than 3% of new homes built each year in the state are constructed with adobe, the number usually averages between 500 and 600 dwellings. From examination of building permits in New Mexico and discussions with local architects, realtors, and planners throughout the Southwest, it appears

that most of new adobe dwellings are built for high-income customers. The houses usually contain above-average square footage with the addition of extensive southwestern architectural details and style. In some areas, particularly in parts of rural northern New Mexico, many backyard adobe producers build their own homes (McHenry 1985). This is often done on a part-time basis, and the house is completed without extensive debt or long-term mortgage payments.

Before 1970, most adobe buildings were built with traditional adobes. A breakdown of New Mexican adobe-brick production in 1987 shows that 27% were traditional (untreated) bricks, 68% were semistabilized bricks, and 5% were stabilized bricks (Smith and Austin 1989). Since the 1980s the percentage of semistabilized bricks has increased at the expense of traditional adobes.

Today, most builders purchase adobe bricks from commercial yards located throughout New Mexico. The principal, standard-size adobe brick produced and used in New Mexico measures approximately 10 × 25 × 36 cm and weighs approximately 13.6 kg (Smith and Austin 1989, 1996).

Latin America

Earthen and stone construction has been the dominant building style throughout Latin America, except in areas where timber and wood products are also available. In Central America today, rural people commonly tend to build adobe houses and structures rather than use readily available wood products. Urban areas in Latin America are heavily inclined to concrete construction and stick (wood-frame) housing, but rural areas still rely on a mix of stone, concrete, and earthen construction, depending on the availability and cost of materials. It is estimated that 35 million people live in earthen housing in the Andean region. Although the low cost of such housing greatly benefits the residents, the buildings are vulnerable to earthquake damage, with the associated mass deaths.

Australia

During the last two centuries, brick, stone, and, more recently, concrete construction has dominated urban areas of Australia. Rural construction has been mostly wood frame housing and earthen construction. Corrugated iron roofing is common throughout the country. Enough Australian forests have been largely cut down that the remaining forest lands are being preserved as national parks and recreational reserves. Because of this, most lumber and other forest products are now imported into the country from Indonesia and the island nations (e.g., Papua New Guinea) immediately to the north. As a result, rammed-earth construction is rapidly becoming a style of choice in both rural and suburban areas. Schools, churches, wineries, and much new housing in Western Australia are being built with rammed earth.

North Africa and Middle East

Stone and earthen construction have dominated North African and Middle Eastern construction since the dawn of civilization, supplemented only in the past century by abundant concrete construction. There are no other construction material alternatives in these countries. Rural areas in particular have mostly earthen construction, which is also desirable in countries where air conditioning is prohibitively expensive. Multistory earthen construction is common in some of the emirate cities around the Persian Gulf, dating back many centuries.

South Asia

South Asia, including India, Pakistan, Afghanistan, and a few adjoining countries, relies heavily on earthen and stone construction.

Urbanized areas with long distances to natural earth materials have shifted more to concrete, which is used to build high-rise buildings, major highway systems, and huge residential areas. Earthen building, however, is traditionally important to the Indian and Pakistani cultures. With their combined populations making them the second most populous countries after China, the future holds enormous potential for locally centered earthen building.

China and Interior Asia

Earthen construction is still very common throughout China, particularly in rural and lower-income urban areas. Concrete dominates urban construction and China is the world's top producer and exporter of cement, partly a result of the decimation of China's forests for fuel over many centuries. Interior Asia, which includes Tibet, Mongolia, and various "stan" countries, relies heavily on stone and earthen construction, using concrete only for the small number of highways, institutional buildings, airports, and such. Choice of construction materials is primarily determined by the pattern of their availability over time. An exception in Mongolia and other countries, but still related to traditional use, are yurts and other animal-skin tent housing.

Europe

There is a long history of earthen construction across Europe, and today it is thriving in such countries as Hungary, Bulgaria, and Poland where raw materials are readily available and people cannot afford expensive housing. Europeans have long preferred stone and brick construction in housing, but the reality of high-cost construction material is forcing them more and more to alternate materials. Only in northern lands, where wood is still readily available, does housing employ a greater amount of wood.

Sub-Saharan Africa

As the most economically disadvantaged location in the world, Sub-Saharan Africa depends on whatever materials are available for building. In many rural areas this is adobe construction, commonly complemented by thatched roofs, woven sticks, corrugated iron roofs, and other nonearthen alternatives. When adobe structures are constructed with these alternatives, the relatively few earthquakes that occur in seismically active areas in this region do not automatically result in mass collapse of walls and roofs. Judging by the grim economic future of this area, earthen construction will remain a dominant rural building style in the future.

ECONOMIC FACTORS

Cost

In New Mexico, adobe brick production varies from a labor-intensive, traditional technique using a hoe, shovel, and wheelbarrow to a mechanical large-scale operation producing 5,000 to 20,000 bricks per day. The production of adobe bricks is seasonal and is usually limited by the number of frost-free days for a particular adobe yard. In New Mexico, the production season lasts from 5 to 9 months, depending on local climate and weather conditions.

Smith and Austin (1989, 1996) reported that producers using the handcraft technique for traditional (untreated) adobe marketed their products at 21 to 40 cents per brick at their yards. One-person commercial yards produced 100 to 300 bricks per day. Semimechanized adobe yards with 8 to 10 employees can produce 5,000 to 6,000 semistabilized bricks per day that are sold for 30 to 35 cents per brick at the adobe yard (Figure 8).

In 2004, the largest mechanized adobe yard in New Mexico (the Adobe Factory in Velarde), which has 3 to 6 employees, produced up to 24,000 semistabilized adobes per day, which sold for

Figure 8. An adobe lay-down machine at an adobe yard in northern New Mexico. A front-end loader places the adobe mud in the hopper, which moves over the form, filling the spaces. The form is then retracted and the machine moves on.

72 cents each at the adobe yard. The same producer also sells traditional adobe for 72 cents each, but fully stabilized adobe is sold at 90 cents. Other producers say that the stabilizers (asphalt emulsion and portland cement) add between 15 and 20 cents to the price of an adobe brick. Pressed-earth blocks in a production yard are sold for comparable prices, but some producers take their machine to the job site and use local soil for their blocks at a slightly reduced price. These producers are the contractors as well and build the desired walls.

Markets in the American Southwest

Tradition is the most important factor in determining markets for adobe materials. In areas that have a strong history of mud construction, adobe is a appealing and even preferred. In other areas where the population is not familiar with adobe or considers it "lower class" to live in such buildings, new adobe buildings will not replace the old ones that disappear. Santa Fe is an example of a traditional adobe area, where the "Santa Fe style" of construction is adobe pueblo and territorial style (Smith and Austin 1989, 1996). Adobe buildings are preferred by many wealthy landowners and contractors who use other types of construction to mimic the adobe styles.

In nearly all other parts of the United States, mud construction is not popular and there is virtually no new construction with this method. In Great Britain, France, and Germany, countries with long histories of earthen construction, mud construction is no longer used, even though excellent examples of multistoried rammed-earth buildings still exist.

Transportation

Although adobe may be made on the construction site, it is now more likely to be made in adobe yards and transported to building sites on flatbed trucks (Figure 9). Larger flatbed trucks carry about 5,000 palletized or stacked adobes. Although transport to distant construction sites is uncommon, some producers ship adobes several hundred miles. The reason for the long transport of adobe blocks is not because of the lack of the raw, native materials, but because contractors in some areas of the country have neither the training nor the talent for this type of construction.

Rammed-earth construction methods require that the walls be made at the building site. Consequently, the typical method of

Courtesy of Edward W. Smith.

Figure 9. A truckload of adobe bricks on pallets ready for delivery in northern New Mexico

construction is to use local materials or materials that have not been transported far.

ALTERNATIVE AND COMPLEMENTARY MATERIALS

The most commonly used alternative material is concrete block. Even in the American Southwest, many adobe-style homes are constructed of stucco-clad concrete block. Although smaller and lighter than adobe and easy to use, concrete block walls do not have the physical properties of thicker adobe walls and must be carefully insulated to achieve consistent temperature and sound-deadening properties similar to those of adobe.

Complementary materials also can be used to make adobe blocks. These materials include "off-spec" aggregate plant products, ditch dredgings, fly ash, shredded tires, reject clays, and other fine-particle products and similar "waste" products that would otherwise have a disposal cost. Such materials are already commonly used in concrete manufacturing, so there is an established practice in such by-product use. Using complementary materials in adobe or earthen construction has a threefold advantage:

1. They are inexpensive as aggregates and filler materials.
2. They may contribute physical advantages to the finished product (e.g., pozzolanic effects, and greater tensile strength).
3. They resolve another producer's disposal problems and may solve environmental problems in the process.

In underdeveloped countries, sometimes the lack of availability and the higher cost of cement can make adobe the preferred type of construction. The use of available native materials can be a strong incentive in countries where builders are short of funds to buy cement or construct cement plants.

GOVERNMENTAL CONSIDERATIONS

In the U.S. regions where adobe is widely used in construction, locally adopted amendments to the Uniform Building Code establish building specifications. In the New Mexico code for adobe, which was last completely modified in 1988, acceptable earthen construction materials and products and the tests necessary for their use are listed and explained. Earthen construction specifications have been similarly codified in other states.

Health and Safety Regulations

Seismic Activity
